CONTROVERSIES REGARDING SYPHILIS

STATISTICS AND CLINICAL IMPRESSIONS *

W. H. GUY, M.D.
PITTSBURGH

Experience is often misleading and clinical impressions are often fallacious; limited and unanalyzed statistics are of no more value than faulty clinical impressions. These facts are nowhere better exemplified than in a review of the literature with reference to certain controversial statements concerning syphilis. Has the incidence of syphilis been increasing or diminishing? Is neurosyphilis more frequent since the advent of arsphenamine? Is the incubation period of neurosyphilis shorter since the introduction of the arsenicals? Are the arsphenamines neurotropic? Is optic atrophy more frequently seen following arsenical therapy and is arsphenamine contraindicated when optic atrophy has developed? These are but a few of the questions that lead to futile debate. Honest opinions of dependable clinicians are widely divergent. In an attempt to arrive at some conclusions independent of personal opinions and prejudices, numerous sources of information have been invoked to centralize data into one communication bearing on the foregoing questions. The first fact to emerge from a formidable list of articles reviewed was that, while clinical impressions are of value, they are not at all reliable. Taking one question as an example, of fifteen articles presenting conclusions based on personal impressions, eight opinions of eminent scientists were diametrically opposed to those of seven equally prominent authors. Statistical studies tended more toward uniformity and therefore only statistics or opinions with a statistical background have been utilized in this paper.

THE INCIDENCE OF SYPHILIS

Statistics on the incidence of syphilis in general are difficult to obtain. In only a few instances are venereal diseases reported except in the armies and navies. Chart 1 was compiled from the incidence of syphilis in the various armies and navies of the world plus data from the civil population in a few countries.

A reduction in the incidence of syphilis is therefore apparent in late years that must be more than apparent considering the increased interest in the subject and refinements in diagnostic procedures. It is difficult to explain the peaks and low levels in the incidence curves. Contributary to the high incidence rates in chart 1 were the high figures supplied by armies of occupation. Figures from the military forces of the same countries at home or during actual warfare were much lower. But marked fluctuations are the rule for all statistics. Thus in Denmark,[1] where legal control exists, the same phenomenon is to be noted. Sweden [2] records a recent increase. The hospital St. Louis reported an increase of 150 per cent in 1925 over 1924. Jeanselme [3] thought the large immigration of foreign workers a factor in this instance. Incidence peaks in certain countries corresponded to war dates but as often did not. During and immediately following the World War a general increase is to be noted. Unfortunately, in several of the largest units no figures are available for this period. Statistics from the forces of the United States form the basis of chart 2.

While a moderately increased morbidity is to be noted in the military forces of the United States during and immediately following the World War, the peak does not compare to those developed when the country was not at war. But statistics from military forces do not necessarily indicate the incidence rate for the civil population, and accurate data from the latter sources are difficult to obtain. Reports from the League of Nations in 1927 and 1928 indicate a decrease of syphilis in general with an increase in a few instances. Gumpert,[1] utilizing these reports for an epidemiologic forecast, thought that modern treatment would never eradicate syphilis. Almquist is quoted to the effect that marked variations are bound to occur and that the peak of the reactive epidemiologic curves are more marked, the greater the dip in the curve. Gottstein is quoted as saying that for all epidemics the law of waves must prevail. Seasonal fluctuations, cultural influences and exhaustion of susceptible material also enter into the question. In military life the influence of prophylaxis and the removal of sources of contagion by prompt treatment of infected individuals is to be considered. Jadassohn [4] reports that in fourteen countries with a total of fifty sources of information a general decrease in the incidence of syphilis in recent years is attributed to modern methods of treatment, particularly with arsphenamine.

THE MORBIDITY, INCUBATION PERIOD AND MORTALITY OF NEUROSYPHILIS

Numerous authors, usually from personal clinical impressions, assert that neurosyphilis is on the increase, and they attribute this increase to the general use of arsphenamine. Most authors dealing with statistical

studies from Germany,[5] Austria,[6] Hungary,[7] Czechoslovakia,[8] Switzerland,[9] France[10] and Denmark[11] are guarded as to the value of their statistics but in general report a stationary or decreased incidence of dementia paralytica covering a period from 1900 to 1922. For instance, Bumke, from admission data of all the clinics of Saxony, reported 13 per cent patients with dementia paralytica for 1915, and 14 per cent for 1918, the rate falling steadily to 8 per cent in 1922. Combined statistics from Bavarian clinics showed the proportion of patients with dementia paralytica approximately the same over a term of years. A moderate increase in the incidence of dementia paralytica is to be noted in numerous statistical reports covering the period of 1905-1916-1918 following by gradually decreasing figures up to 1922. It is suggested in more than one communication that the early increase previously noted may be illusory or real in view of the introduction of the Wassermann reaction and lumbar puncture, and the acceleration in the appearance of neurosyphilis as the result of inadequate arsphenamine therapy.

Table 1.—*Mortality from Syphilis*

	1917	*1923*
Australia	8.2	7.2
England	14.6	9.9
United States	20.0	16.7
Italy	18.0	13.2
Netherlands	8.1	5.7

In the United States[12] as a whole, cases of dementia paralytica in 1910 constituted 6.4 per cent of admissions to hospitals for mental disease and, in 1922, 7.9 per cent, according to the bureau of the census. The increase noted in 1922 over 1910 is offset as noted in the census report by virtue of the fact that the 1910 figures from some states were so low that the data must be considered incomplete. Thus, eleven states reported less than 2 per cent, and four states did not report any admissions for dementia paralytica. It is interesting to note that in New York State admissions for dementia paralytica rose from 7.82 per hundred thousand of the general population in 1922 to 8.02 in 1928, and during the same period the mortality per thousand deaths fell from 5.28 to 3.89. In Massachusetts the rate fell from 8.31 in 1908 to 6.41 in 1928 and the death rate over the same period from 5.87 per hundred thousand of population to 4.72. In the United States[13] as a whole, mortality for tabes and dementia paralytica per hundred thousand fell gradually from 8.2 in 1921 to 6.4 in 1927. Over the period 1922 to 1928 in England[14] and Wales the death rate per hundred thousand for dementia paralytica fell from 4.44 to 3.57. *Health News*[15] supplies the figures on the mortality from syphilis, including tabes and dementia paralytica, given in table 1. The statistics on the incidence and mortality from tabes show the same trend as those on dementia paralytica.

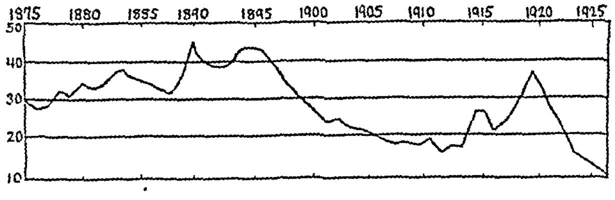

Chart 1.—Incidence of syphilis per thousand available figures in the combined armies and navies of the world from 1875 to 1926. The greater portion of the statistics were obtained from Jadassohn's Handbuch der Haut- und Geschlechtskrankheiten, Berlin, Julius Springer, 1927.

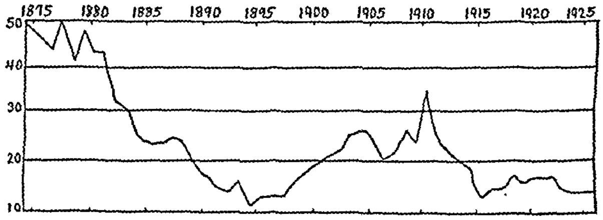

Chart 2.—Incidence of syphilis in the United States Army and Navy from 1875 to 1926.

It may be stated, then, that from the available data on dementia paralytica and tabes a slight decrease or an almost stationary rate is obtained covering the period since the advent of arsphenamine, and that during the same period the mortality from these sources has definitely decreased.

Statistical studies as to the frequency of acute cerebrospinal syphilis before and since arsphenamine are not numerous but are in general agreement. Pette,[16] from a survey of the material at Nonne's clinic, concludes that early neurosyphilis unquestionably became more frequent after the introduction of arsphenamine. In about 50 per cent of cases, cerebrospinal syphilis appeared during the first year, most frequently from two to three months after infection. However, it is to be noted that the cases were insufficiently treated; in only three cases did neurosyphilis of this type develop in spite of treatment. Lauter[17] analyzed neurosyphilis at Strümpell's clinic from 1900 to 1922, including only cases with clinical signs, with the results shown in table 2.

Table 2.—*Occurrence of Neurosyphilis*

	Interval Between Infection and Appearance of Clinical Symptoms

He concluded that, since the introduction of arsphenamine, early involvement of the central nervous system had become more frequent. Marburg[18] reported concerning the relationship between treatment and incubation time in a group of patients with dementia paralytica, those with tabes and those with early cerebrospinal syphilis and showed a shortening of the incubation period in the arsenical treated group. Mattauschek,[19] in 1924, reported an increase in cerebrospinal syphilis and a stationary curve for dementia paralytica. Hyder[20] found the average incubation time for neurosyphilis among a group infected prior to the introduction of arsphenamine to average fifteen years, and among a group infected during the arsphenamine era to be seven years. In respect to the apparent increase of cerebrospinal syphilis and the rather definite shortening of the incubation time of neurosyphilis, most communications based on clinical impressions are in agreement with those based on statistics, but the interpretation of these phenomena are widely divergent. A large number of authors unqualifiedly condemn arsphenamine, but in statistical studies in which the incidence and incubation periods of neurosyphilis were compared following treatment with mercury alone, mercury combined with arsphenamine, arsphenamine alone, or no treatment, have demonstrated that insufficient treatment of any kind in the early stages of the infection predisposes to involvement of the central nervous system.

Stokes and DesBrisay[21] found no marked difference in the absolute incidence of neurosyphilis among cases untreated, mouth treated and inadequately treated by modern methods, but thought that neurosyphilis had a much larger proportionate incidence in the last group. A group of authors too numerous to mention show that with intensive and persistent treatment, regardless of its type in early syphilis, the tendency toward neurosyphilis is diminished. Moore,[22] in a study of eighty-one cases of neurorecurrence, concluded that the condition is practically confined to inadequately treated patients and showed that increase in the amount of treatment, including arsphenamine, reduces the incidence of neurosyphilis. These apparent facts are given added weight when compared with the experimental production of various types of disease by Pearce and Brown[23] using subtherapeutic injections of arsphenamine. Considering the entirely inadequate treatment that the majority of patients with early syphilis receive, and the demonstrated trend of such cases, it is not surprising that there is an increase in the number of neurorecurrences, and that the average incubation period of neurosyphilis has been shortened.

ARSENIC IN OPTIC ATROPHY

An article by Abadie[24] on the evils of arsenic and bismuth in ocular syphilis is one of several articles by prominent writers condemning arsenic in syphilitic disease affecting the eye. The author states that chorioretinitis and optic atrophy have become infinitely more frequent since the introduction of arsphenamine. He states that not only are arsenic and bismuth compounds absolutely powerless to modify the evolution toward blindness but they often precipitate it. He reports shortening of the incubation period, and recommends intravenous injections of mercuric cyanide as the best form of treatment. Arlt[25] of Uhthoff's clinic reports a decrease of optic atrophy since the introduction of arsphenamine and naturally favors its use. All of the fifty-three cases of optic atrophy at this clinic had been inadequately treated early in the disease, and later on they had received mercury almost exclusively. Igersheimer[26] reports no unusual hazard to either the healthy or the diseased eye, but at the same time thinks that the drug is of no particular service in optic atrophy. Zimmerman[27] states that the only true toxic arsphenamine reaction involving the normal eye is a conjunctival hyperemia. There are no clinical or experimental data indicating that arsphenamine unfavorably affects the normal optic nerves or the retina. However, serious consequences may follow the exhibition of arsphenamine in extensively diseased eyes in the form of a Jarisch-Herxheimer reaction.

The aggravation of existing pathologic conditions by arsphenamine can in the majority of cases, as has been repeatedly demonstrated, be avoided by the preliminary use of mercury or bismuth and the iodides. Fehr, quoted by Zimmerman, reported a study of 340 cases treated with a single injection immediately following the introduction of arsphenamine. Of these, thirty-two developed evidence of ocular recurrence, eleven of which were optic neuritis. Moulton[28] reported a case of methyl alcohol blindness cured by the administration of small doses of neoarsphenamine. Stock[29] obtained good results by treating retrobulbar optic neuritis from various causes with arsphenamine. Suker[30] treated four cases of methyl alcohol blindness with arsphenamine and all the patients recovered. It would seem, then, that a deleterious effect on normal eyes or those affected by nonsyphilitic disease has not been demonstrated. Neymann and Singleton,[31] in reporting fifty cases of neurosyphilis, recorded the administration of forty, thirty-two and twenty-four injections of tryparsamide to three patients with optic atrophy, resulting in stationary vision and serologic improvement in two. Transitory amblyopia was noted in 10 per cent of the entire series of cases, with a permanent reduction of vision in three cases. In 152 cases, Stokes and Wilhelm[32] reported 8 per cent visual disturbance with tryparsamide, 5.4 per cent with objective evidence of damage, *and in one case a reduction to tubular vision.* Lillie[33] and O Leary with Becker[34] reported similar results, pointing out that syphilis would in part account for these reactions.

Apparently in this arsenical a hazard exists which is not paralleled by any other salt of arsenic now used in the treatment of syphilis. In the clinic of the University of Pittsburgh from 1923 to 1929 there were received approximately 50,000 cases, and of these 1,917 cases presented ocular syphilis of different types. Twenty were found with optic atrophy. The average interval between infection and examination, where available, was eighteen years. All cases were treated with mercury, iodides and arsphenamine. The average amount of treatment was one eight weeks' course and in only half of the cases are complete notes on the condition of the eyes available after one year's time. Of these, one showed marked improvement serologically and in the perimetric field. In four no change was noted, and in the remaining cases gradual deterioration developed. No patient was given arsphenamine for the first treatment, either mercury or bismuth with iodides being used to reduce the hazard of Herxheimer reaction.

If these figures demonstrate anything other than that we were unable to control our patients, it is that carefully administered routine treatment including arsphenamine frequently controlled by examination of the eyes is not contraindicated by the presence of an optic atrophy. Lederer[35] reviewed the work of Leber, Wecker, Uhthoff, Hippel, Hirschberg, Igersheimer and Behr, and reported personally on the treatment of two cases of optic atrophy which he treated with foreign protein, sodium nucleinate, arsphenamine, mercury and malaria over a period of from three to four years with improvement in vision and fields in three eyes and failure in two. Stargardt,[36] from a study of optic atrophy in tabes and dementia paralytica, concluded that atrophy was secondary to a round cell infiltration of the intracranial portion of the optic nerve and argues the presence of spirochetes as the direct cause in contradistinction to the theory of toxic origin.

From the foregoing and in view of the irregular and incalculable course of the condition, it would be unwise to speak of successful treatment unless arrest or improvement holds for at least two years. Treatment, to be effective, must be early and intensive. As long as inflammation and exudation are associated with the process, one may expect arrest or improvement, but with established atrophic degeneration one must face the fact that scar cannot be replaced by normally functioning tissue. Whether optic atrophy is purely toxic in origin and essentially atrophic in character or due to the presence of the spirochete and inflammatory exudate is of relative unimportance. The question in point is whether or not arsphenamine or any other arsenical used in the therapy of syphilis is prone to precipitate or aggravate optic atrophy. Barring the Herxheimer type of reaction, such possibilities seem rather remote in view of the foregoing, but the question arises as to whether the rapid clearing of exudate may lead to more scarring than would result from the use of mercury, bismuth and the iodides. Should such be the case, acute eye lesions seen early in the course of syphilis and treated with arsphenamine should show this tendency. Baruch[37] reviewed 10,000 cases with an incidence of 3.67 per cent of optic neuritis, all treated intensively with arsphenamine to complete cure in all, and with a secondary atrophy in only two cases. It would seem that while tryparsamide must be used cautiously with reference to pathologic conditions affecting the eyes, the trivalent arsenicals carefully used with due caution are at least not contraindicated in the presence of an optic nerve involvement.

IS ARSENIC NEUROTROPIC?

Perusal of the literature reveals the misuse of the word neurotropic. A great many perfectly clean-cut cases of Jarisch-Herxheimer reactions are ascribed to neurotropism on the part of arsenic. Neurorecurrences are also credited to the neurotropic effect of arsenic. Practically every neurologic accident has from time to time been considered due to neurotropism of arsenic. Dorland[38] defines neurotropism as "having a chemical affinity for nervous tissue." Therefore, if the term is to be used correctly, it must be limited to conditions in which some particular tissue or organ binds more arsenic than others. Thus, if the peripheral neuritis occasionally seen as a complication of arsenical medication could be shown to be associated with a selective localization of arsenic, an example of neurotropism would be established. Arsphenamine seems to have no selective affinity for the nervous system; in fact, one of the difficulties is to get the drug in contact with the diseased structures in syphilitic involvement of the central nervous system. Ullmann[39] by animal experimentation found only a trace of arsenic in three brains, and none at all in two, in contradistinction to the arsenical content of other tissues, following intramuscular injections of the drug. Similar results are reported by Bornstein[40] and by Morel with Mouriquant.[41] Voegtlin and Smith,[42] using single large doses of arsphenamine, found 1.16 mg. per gram of fresh brain; in the cerebrospinal fluid, 7.21 mg. (normal fluid content is from 0.5 to 1.55) while there was in the spleen 16.85, bile 195.54, liver 16.17, stomach and intestines 10.34 and blood 5.25 mg. per gram of fresh material. Engelman[43] demonstrated that arsenical storage in the brain which, following administration paralleling ordinary therapeutic procedures, revealed at most only a trace, could be increased only by frequent administration of large doses over a period of several weeks. And still small doses of arsenicals are said to be frequently neurotropic. The point to be made is that all sorts of accidents may complicate arsenical medication of syphilis, but proof does not exist that they are due to neurotropism on the part of arsenic. If it is considered that the small amount of arsenic deposited in the nervous system produces symptoms referable to these tissues, neurotoxic would seem to be the better term.

This paper, dealing with generalities, is perhaps suggestive, but I prefer to think not at all conclusive. It is hoped that it may serve to stimulate research that will be conclusive.

RESULTS OF VARIOUS OPERATIONS FOR PROLAPSE OF THE UTERUS *

VIRGIL S. COUNSELLER, M.D.
AND
LEDA J. STACY, M.D.
ROCHESTER, MINN.

Of the various operations for prolapse of the uterus, those most used probably are the Watkins-Wertheim, the Mayo vaginal hysterectomy, the Kocher fixation, the modified Gilliam, and various other types of intraperitoneal shortening of the round ligaments combined with vaginal plastic operations. The technic of each has undergone various modifications and is described in detail in the literature. The value of any one of these procedures as a corrective operation is determined largely by the results obtained from its use, by the ability of the surgeon to execute the technic correctly and by its application to the properly selected case.

Masson[1] has stated that the choice of operation depends on several factors. Chiefly these are: the age of the patient, her marital state, the risk of an abdominal or vaginal operation, and the degree of prolapse with its accompanying symptoms. The practice of using an operation as a routine is to be condemned, since it would be obviously too radical in some cases and certainly inadequate in others.

Cystocele and rectocele, which are the accompanying conditions of prolapse, are usually the factors which induce the patient to seek relief. The prolapse of the uterus itself may be symptomless. The associated cystocele usually is in direct proportion to the extent of prolapse. Such conditions also occur in the nulliparous woman and are usually due to congenital or developmental defects in the supporting ligaments, the muscles, and the fascia of the pelvic diaphragm. As the uterus becomes retroverted and descends, in women who have had children the bladder is carried downward, because the uteropubic fascia, which previously supported the bladder in its normal position, is dragged downward on the cervix.

All writers agree that injury produced at the time of childbirth is the most common cause of prolapse and its accompanying disorders. Failure to repair adequately the soft parts at the time of labor or soon thereafter is of course an incidental and related cause of the condition. The atrophy of the pelvic viscera and the loss of tonus of the pelvic muscles after menopause account for the increase in number of cases of prolapse after this period. Prolapse in the nulliparous woman usually occurs after the menopause because of this atrophy of the soft parts in addition to congenital defects. Any procedure, therefore, which is used for the correction of prolapse must be directed to the correction of cystocele or must be supplemented by anterior colporrhaphy, and the pelvic floor must be reconstructed in all cases if cure of the prolapse is to be expected.

The patients are always divided into two main groups: those who are in the child-bearing period, and those who are past the menopause. Practically all gynecologists are in accord regarding the treatment of the first group, which consists in repair of the cervix, of the anterior and posterior vaginal walls and of the perineum, combined with some type of intraperitoneal shortening of the round ligaments. The treatment of the second group is the subject of a great deal of discussion, and many operations have been devised and modified. In our estimation comparatively few types of operations are necessary for the adequate treatment of these cases. However, an occasional case may present certain complicating features which may be better cared for by a method not mentioned here. For instance, it may be best to use such an operation as subtotal or total abdominal hysterectomy followed by implantation of the cervix or vaginal vault in the abdominal wall, or the Le Fort operation in which the vagina is obliterated. Only a small number of the total group will require such procedures for prolapse, and for this reason consideration of them is omitted here.

There is no accepted standard for the classification of various degrees of prolapse. Certain gynecologists have designated the extent of the prolapse as first, second and third degrees, but this classification has not been generally accepted. It would seem that since in recent years it has become the custom to grade lesions on a basis of 1 (slight) to 4 (extreme), it would be logical to grade uterine prolapse and its accompanying disorders on the same basis. A division of the cases according to this method contributes to a better understanding of the extent of the lesion and aids one in selecting the type of treatment which should be applied. All cases of retroversion and only slight descensus of the uterus should be classified in group 1; cases in which the cervix is presenting at the introitus (not cervical elongation), in group 2; cases in which the cervix projects partly from the introitus, in group 3, and cases in which there is complete prolapse of the cervix and uterus, in group 4. The extent of cystocele and rectocele, and of retroversion, could also be graded on a basis of 1 to 4.

The results submitted here are all graded according to this proposed classification. The patients were treated, by various members of the surgical staff of the Mayo Clinic, by the Mayo vaginal hysterectomy, the Kocher type of abdominal fixation, the Watkins-Wertheim interposition operation, and the modified Gilliam technic or various other methods of intraperitoneal shortening of the round ligaments.

The data were obtained from questionnaires sent to 819 patients, 83.5 per cent of 980 such patients treated at the Mayo Clinic from 1920 to 1928 inclusive. Therefore, unless a patient was treated two years or more before the time when the questionnaire was sent, her case is not included. The average age of the patients who underwent vaginal hysterectomy was 54 years; the Kocher operation, 52 years; the Watkins-Wertheim operation, 49 years; the modified Gilliam operation, 33 years, and intraperitoneal shortening, 33 years. The average age of patients of the entire group was 51 years. This average is practically identical with the figures given in the literature. Analysis of the figures by half decades of life reveals that the largest number of patients who are past the menopause and who seek relief are between the ages of 45 and 60 years and that the greatest number who are in the child-bearing period are between the ages of 25 and 35 years. The incidence of prolapse, as regards the number of children born, is important, as is shown in table 1. The largest number of children were borne by those patients who were treated by the method of vaginal hysterectomy, and the largest number (seventeen) of nulliparous women of the entire series were treated by this method.

ASSOCIATED OPERATIONS

The number and proportion of operations for conditions associated with uterine prolapse are shown in table 2. It will be noted that perineorrhaphy was performed in a large proportion of cases. The largest number of vaginal plastic procedures occurred in association with the modified Gilliam operation and the other types of intraperitoneal shortening. Further reference to these operations will be made in the consideration of each operation.

MAYO VAGINAL HYSTERECTOMY WITH AND WITHOUT PERINEORRHAPHY

Of a total of 696 patients who underwent vaginal hysterectomy, 576 (82.75 per cent) were heard from. The patients who were entirely free from symptoms were classified as having obtained good results, and those who were only partially relieved, as having obtained fair results. In the latter group the patients all stated that their condition had been tremendously improved by the operation but that they continued to have occasional attacks of cystitis. Good results occurred in 76.74 per cent, fair results in 20.48 per cent: thus satisfactory results were obtained in 97.22 per cent (table 3). In chart 1 are represented graphically the degrees of prolapse on a basis of 1 to 4, by half decades of life ranging from ages 25 to 75 years; the results are expressed as averages in percentage for each half decade of life. There were sixteen failures or poor results in 2.78 per cent of the patients. All of these had prolapse and cystocele graded 3 or 4 preoperatively, and complained of recurring prolapse of the bladder within a few months after the operation. Of the 696 patients, 14 died, a hospital mortality of 2.01 per cent (table 3). Studied by half decades, the largest number of cases are seen to have occurred between the ages of 55 and 60 years, with 93 per cent occurring at or beyond the menopause. The percentage of satisfactory results is practically the same for each half decade; it ranges between 94.02 and 100 per cent.

Table 3.—*Mortality in Hospital and End-Results of Operation for Prolapse of the Uterus, 1920 to 1928*

	Entire Series				Questionnaires Answered				
		Mortality in Hospital					End-Results		
Type of Operation	Cases	Cases	Per Cent	Average Age, Years	Cases	Per Cent	Good	Fair	Poor
Vaginal hysterectomy	696	14	2.01	54.05	576	82.75	76.74	20.48	2.78
Kocher	92	..	....	52.00	78	84.78	66.67	28.20	5.12
Watkins Wertheim	71	..	....	49.11	59	83.09	69.49	27.12	3.39
Modified Gilliam	77	1	1.29	38.07	70	90.90	60.00	28.57	11.43
Intraperitoneal shortening of round ligaments	44	1	2.27	33.61	36	81.81	63.89	27.78	8.33
Total	980	16	1.62	51.16	819	83.57	73.26	22.71	4.03

Perineorrhaphy was performed in all cases except when the perineum had been repaired previously elsewhere and secondary repair was not necessary (chart 1).

KOCHER OPERATION

Of a total of ninety-two patients treated by the Kocher fixation method, seventy-eight (84.78 per cent) were traced (chart 2). Good results occurred in 66.67 and fair results in 28.20 per cent: thus satisfactory results occurred in 94.87 per cent. There were poor results in four cases (5.12 per cent). Three of the patients had undergone previous vaginal plastic operations combined with internal shortening of the round ligaments for cystocele and rectocele graded 2 and 3, with prolapse graded 1. Symptoms of prolapse, with irritability of the bladder, recurred within a year in three cases. One patient was completely relieved for one year but recurrence developed following repair of postoperative abdominal hernia. The probability of cure of each of the four patients who had recurrence was doubtful at the time of operation, because they were all obese, the fascia of the abdominal walls was very thin and the rectus muscles were separated. There were no deaths in the hospital. The average age of the patients was 52 years; the age of the youngest was 30 and of the oldest, 70 years (chart 2).

WATKINS-WERTHEIM OPERATION

Seventy-one patients were treated by the Watkins-Wertheim interposition operation. Replies to inquiries (chart 3) were received from fifty-nine (83.09 per cent). The average age of the patients in this group was 49 years. Fifty per cent of the patients were between the ages of 40 and 55 years, with the largest number between 45 and 50 years. There were no deaths in the hospital. Good results occurred in 69.49 per cent and fair results in 27.12 per cent; thus satisfactory results occurred in 96.61 per cent. The majority of the patients had prolapse graded 2 and 3, with the greatest number graded 2. The degree of cystocele averaged between grades 2 and 3. The results for cystocele and prolapse correspond. Poor results were recorded in two cases (3.39 per cent). Each of these patients was aged 54 years. One patient had borne six children and the other, two. Both had cystocele and prolapse graded 2. Recurrence of the prolapse and vesical trouble developed within a few weeks after operation in one case and seven months after operation in the other.

MODIFIED GILLIAM OPERATION

Seventy-seven patients were treated in accordance with the modified Gilliam technic of internal shortening of the round ligaments. Replies (chart 4) were received from seventy (90.9 per cent). The operation was combined with perineorrhaphy in forty-two of the seventy cases (60 per cent), with cervical amputation of the Sturmdorf type in nineteen (27.14 per cent), with cauterization of the cervix in ten (14.28 per cent), with dilation and curettage in fifteen (21.42 per cent), and with anterior colporrhaphy in ten (14.28 per cent). Retroversion was associated with the main condition in practically all cases, and the degree of retroversion usually corresponded with the degree of prolapse. Good results occurred in 60 per cent, and fair results in 28.57 per cent; thus satisfactory results occurred in 88.57 per cent. There were poor results in eight cases (11.43 per cent). Fifty-six per cent of the patients in this group were between the ages of 25 and 35 years. Two patients were aged more than 55 years and cure resulted in each instance. The average age of the patients was 33 years. There was one death in the seventy-seven cases, a mortality of 1.29 per cent. In the cases in which failure resulted, two patients had been pregnant since operation and two had been pregnant twice. The pregnancies were all followed by recurrence of prolapse and cystocele, associated with a bearing-down sensation, frequency, and burning on urination. One patient had recurrence of the prolapse and a bearing-down sensation five years after operation. In three cases recurrence developed within three months after operation.

INTRAPERITONEAL SHORTENING OF THE ROUND LIGAMENTS FOR PROLAPSE

Forty-four patients were treated by a method of intraperitoneal shortening of the round ligaments other than that known as the modified Gilliam type of operation, combined with a vaginal plastic operation. Of this number, replies (chart 5) were received from thirty-six (81.81 per cent). There was one death, a mortality of 2.27 per cent in the forty-four cases. The average age was 33 years. Good results were obtained in 63.89 per cent and fair results in 27.78 per cent; thus, satisfactory results were obtained in 91.67 per cent. The greatest number of patients had prolapse graded 2, but some patients had prolapse graded 3. Five per cent of the patients were younger than 25 years; 22 per cent were between the ages of 25 and 30 years, 28 per cent between the ages of 30 and 35 years, 32 per cent between the ages of 35 and 40 years, and 11 per cent between the ages of 40 and 45 years. No patient was more than 45 years of age. In eighteen (50 per cent) of the thirty-six cases the main operation was combined with perineorrhaphy; in seventeen (47.22 per cent) with amputation of the cervix of the Sturmdorf type; in four (11.11 per cent) with repair of the cervix, and in five (13.88 per cent) with repair of cystocele. There were poor results in three cases (8.33 per cent). In one case a Baldy-Webster type of internal shortening of the round ligaments was performed together with a Sturmdorf type of amputation of the cervix and perineorrhaphy. This patient was not benefited by the operation. In one case a Baldy-Webster type of internal shortening of the round ligaments was performed, combined with trachelorrhaphy and perineorrhaphy, Sturmdorf amputation of the cervix and right salpingectomy. This patient was well for three years when pregnancy occurred, which was followed by complete prolapse. The third patient, a nullipara, was aged 31 years, with prolapse graded 1. Symptoms recurred within a few months.

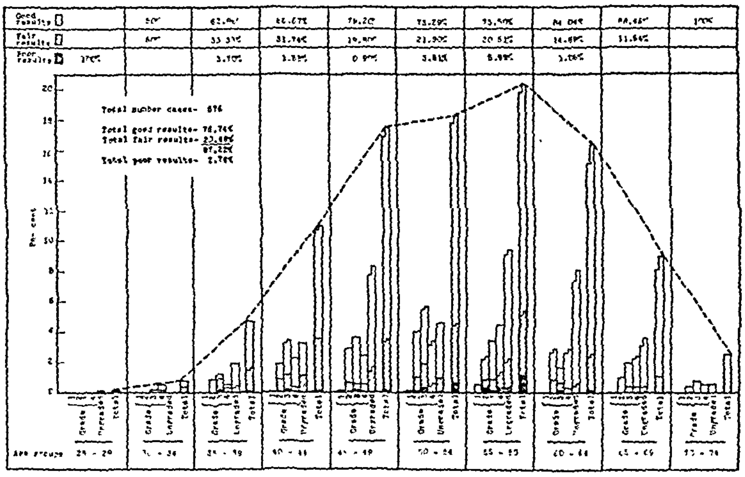

Chart 1.—Mayo vaginal hysterectomy with and without (J) perineorrhaphy.

COMMENT

In this series of 980 patients surgically treated for uterine prolapse and associated conditions, as has been said, answers were received to questionnaires from 819 (83.57 per cent). One hundred and six (12.94 per cent) of the 819 cases occurred in women in the child-bearing period and 713 (87 per cent) occurred beyond the menopause. It is apparent, therefore, that, if these patients do not have sufficient symptoms from prolapse or accompanying cystocele to induce them to seek relief before the menopause, relaxation of the pelvic support and atrophy of the tissues increases their discomfort considerably. Acquired prolapse itself may be symptomless, since it is not uncommon to examine patients with prolapse of the uterus graded 2 to 3 who have no complaints referable to the prolapse. The most distressing symptoms usually are due to the cystocele, which is usually associated with the prolapse. The greater the extent of relaxation of the perineum, the greater will be the extent of prolapse, because the perineum tends to support the uterus within the vagina.

The milder grades of cystocele and rectocele are seen in the child-bearing period associated with a low grade of prolapse and retroversion.

The choice of operation to secure the best results as shown in this study depends on the age, the marital state, and the grade of cystocele and prolapse, and must be one that will relieve the cystocele. If patients have passed the menopause this is satisfactorily accomplished by removing the uterus vaginally, and utilizing the round and broad ligaments to construct a new support for the bladder, as in the Mayo vaginal hysterectomy. In the Mayo Clinic it is the operation of choice when the cystocele and prolapse are of grade 3 or 4. If it is used for the lesser grades of prolapse there is considerable difficulty in approximating the broad ligaments, and this predisposes to recurrence of the cystocele. If the upper edge of the tissue that encloses the approximated broad and round ligaments is firmly sutured to the fascia of the pubic rami, leaving just sufficient room for the urethra, the recurrences will be reduced to a minimum. It is an extremely safe procedure and should be used in elderly women who have passed the menopause and who have large cystoceles unassociated with intra-abdominal lesions. Repair of the pelvic floor was done in 547 (94.96 per cent) of the 576 patients. It was not performed in a small group because the perineums had been repaired previously elsewhere and the repair seemed adequate at the time of the operation at the clinic.

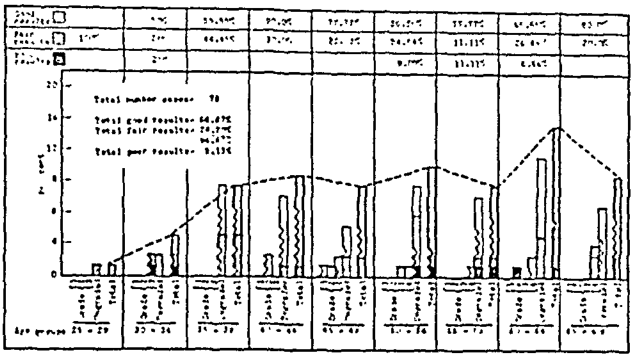

Chart 2.—Kocher operation for prolapse with (>) and without perineorrhaphy.

If the prolapse is of grade 1 or 2, if there is an associated cystocele graded 2 or higher and if it occurs in a patient who has passed the menopause and whose uterus is of normal size, the Watkins-Wertheim interposition operation may be employed. The percentage of satisfactory results obtained at the clinic corresponds closely to that reported by others. Johnson[2] reported thirty-two cases in which cure was obtained in twenty-seven (84 per cent), partial cure in two, and failure in three. Bullard,[3] in an analysis of the treatment of prolapse of the uterus at the Woman's Hospital, New York, reported satisfactory results in 96 per cent of the patients treated by this method. Clute[4] recently reported satisfactory results in 90.56 per cent following personal examination of the patients. Failures that occur are caused by applying the operation in cases in which the patients have severe degrees of prolapse, or an atrophic uterus; this may ultimately result in complete prolapse of the fundus of the uterus, bladder and vagina. The prolapse can be partially overcome by shortening the uterosacral ligaments before the uterus is sutured beneath the bladder. We prefer to confine the procedure to cases with prolapse graded 1 to 2 associated with large cystocele. Repair of the perineum aids in holding the cervix in the posterior position; this was performed in all cases in this group.

For older women who present marked prolapse of long duration with cystocele and rectocele, and who constitute poor surgical risks for extensive operations, the Kocher fixation procedure is excellent. Of the twenty-nine cases in which perineorrhaphy was performed, good results were obtained in 70 per cent, and in those in which perineorrhaphy was not performed good results occurred in 61.3 per cent. The Kocher fixation operation should, therefore, always be supplemented with perineorrhaphy at the time of the operation or soon thereafter unless adequate repair of the pelvic floor has been previously done. In a few of the cases which are recorded in the group of those with good results but in which perineorrhaphy was not done, the perineum had been repaired elsewhere. If there is not too much atrophy of the tissues, and the abdominal wall is firm, perineorrhaphy may not be necessary.

Of the 106 patients in the child-bearing period, seventy-seven were treated by the modified Gilliam type of internal shortening of the round ligaments combined with vaginal plastic operations. Fifty-six per cent were aged between 25 and 35 years. The degree of prolapse, as would be expected, was mostly of grades 1 and 2 with a corresponding degree of retroversion. Nine per cent of all patients with unsatisfactory results were aged between 25 and 35 years. In four of the cases in which the results were classified as failures the patients had recurrence of prolapse of the bladder and uterus following subsequent pregnancies. Another patient was completely cured of her symptoms for five years before recurrence developed. Three patients had recurrence of the prolapse and of the cystocele within three months; one patient had undergone a ventral suspension elsewhere, and the other two patients had remained comparatively free from symptoms by the use of a pessary.

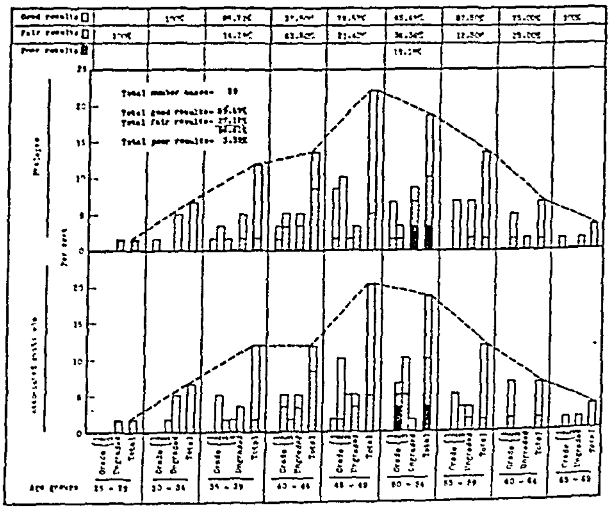

Chart 3.—Watkins-Wertheim operation.

Forty-four patients in the child-bearing period were treated by various other types of intraperitoneal shortening of the round ligaments combined with vaginal plastic operations. Sixty-one per cent of these patients were between 30 and 40 years of age. The degree of prolapse was graded 2 in practically all cases. There were three failures (8.33 per cent). Two of the patients were treated by a Baldy-Webster type of internal shortening of the round ligaments, low amputation of the cervix, perineorrhaphy, and unilateral salpingectomy. Anatomically there was no recurrence after one of the operations but the same symptoms prevailed. The other patient was completely cured for three years, when recurrence occurred following pregnancy. The third patient, a nullipara, was treated by Long's method of intraperitoneal shortening of the round ligaments. Vaginal plastic operations were not performed. Prolapse, graded 2, developed soon after the patient left the hospital; evidently this was a case of congenital prolapse.

[4] Clute, H. M.: Cystocele at Middle Age Treated by the Interposition Operation, New England J. Med. **199**: 994-997 (Nov. 15) 1928.

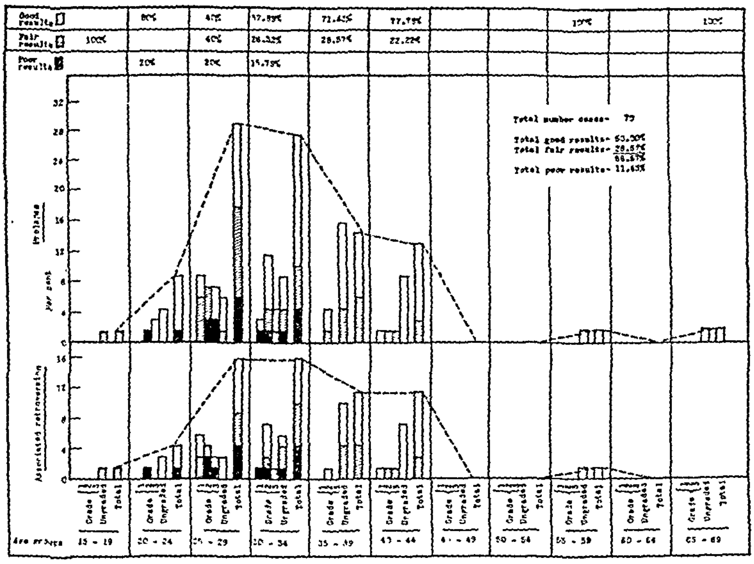

Chart 4.—Gilliam operation.

The results in the group of cases in which the modified Gilliam operation was used were studied separately from those of other types of intraperitoneal shortening of the ligaments combined with vaginal plastic operations because we feel that the Gilliam operation is more compatible with pregnancy. The incidence of pregnancy in the two groups has not been studied. It is seen by comparing the two groups that the operative results for prolapse are essentially the same in the two, but that of those who underwent the Gilliam operation the greatest number were in the half decade of life between 25 and 30 years, whereas of those who underwent other types of intraperitoneal shortening of the ligaments the greatest number was in the half decade between 35 and 40 years.

SUMMARY AND CONCLUSIONS

The series consisted of 980 patients surgically treated for prolapse of the uterus. Of this number, replies from questionnaires were received from 819 (83.56 per cent). There were sixteen deaths, a mortality of 1.62 per cent in the 980 cases. Satisfactory results occurred in 95.97 per cent of the entire series. Five types of operation were employed.

The modified Gilliam technic of internal shortening of the round ligaments comprised one group, and various other types of internal shortening of the round ligaments combined with vaginal plastic operations comprised the second group of operations used for patients of the child-bearing period. For patients who had passed the menopause, the Mayo vaginal type of hysterectomy, the Watkins-Wertheim interposition and the Kocher abdominal fixation operations were employed. From the results it is shown that the modified Gilliam operation, combined with vaginal plastic procedures, is the operation of choice among all types of internal shortening of the round ligaments when other pelvic operation is not indicated. Satisfactory results were obtained in 88.57 per cent in which the Gilliam technic was used.

The Kocher operation is reserved for that group of patients who are past the menopause, senile, and constitute poor surgical risks and for those who previously have undergone hysterectomy, with prolapse of the cervical stump. Satisfactory results were obtained in 94.87 per cent of the cases in which it was used.

If the uterus is of normal size and there is a mild degree of prolapse, graded 1 or 2, with large cystocele and the patient has passed the menopause, the Watkins-Wertheim interposition operation is successfully employed. Satisfactory results were obtained in 96.61 per cent of the cases in which the operation was used.

When the prolapse is of marked degree and is associated with large cystoceles, and the women are past the menopause, the Mayo vaginal type of hysterectomy is the operation of choice. It was employed in 81 per cent of the patients who had passed the menopause, with satisfactory results in 97.22 per cent.

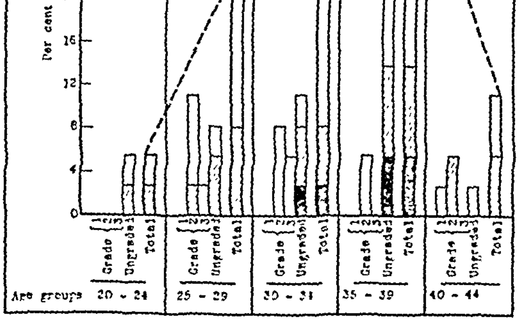

Chart 5.—Intraperitoneal shortening for prolapse.

ABSTRACT OF DISCUSSION

Dr. Carl Henry Davis, Milwaukee: I wish to congratulate the surgeons at the Mayo Clinic on having satisfied 95 per cent of their patients who have this type of condition. The question of grading the descensus of the uterus into 1, 2, 3 and 4, is one that will encounter considerable debate. Many of us think of grade 1 when the cervix comes to the introitus, and consider the large group which the author would put in the proposed grade 1 as in a group in which there is so much normal variation due to position of the bladder and the like that it need not be considered as a degree of prolapse. In the consideration of the cases treated by the modified Gilliam operation, which I believe at the Mayo Clinic is the Simpson subfascial type of shortening, and the other intraperitoneal operations, it would be interesting to know whether or not the uterosacral ligaments were shortened in the cases in which the results were not satisfactory. If the cervix comes down to the introitus, I believe that uterosacral shortening is an important part of the operation. Experience with pessaries should teach that the round ligaments after all are only guy ropes and that holding up the uterus is to a great degree dependent on the uterosacral ligaments. In the cases with ventral fixation, it is possible that some of the poor results were in a group in which there is a ventral fixation without a previous repair of a large cystocele. It is not always possible because of the patient's condition to repair the cystocele but whenever possible one should choose some type of vaginal operation, or the bladder should be advanced before the uterus is fixed to the abdominal wall. My results with vaginal hysterectomy and the overlapping of the broad ligaments as used at the Mayo Clinic have been very satisfactory. I have had no experience with recurrence of cystocele and doubt its recurrence if the broad ligaments are attached high up under the urethra. However, in watching various surgeons do this operation, I have noticed that there is not a uniformity of care in fixing the broad ligaments high under the urethra. I do not believe that the Watkins-Wertheim operation need be ruled out completely in the cases presenting a third degree prolapse. It is, however, to be ruled out except in the cases in which there is a uterus of normal size that is not diseased.

THE TREATMENT OF MALARIA

WITH SOME REFERENCE TO RECENTLY PROMOTED NEW REMEDIES *

C. C. BASS, M.D.
NEW ORLEANS

Cinchona was first introduced to civilized man for the treatment of what we now know was malaria about 1640. For many years thereafter its use was in the hands of charlatans and others who exploited it as a secret remedy for selfish purposes. Its effect in malaria is so definite and so convincing that, regardless of these circumstances, it was more and more widely used and finally accepted as a specific for fevers of almost all kinds.

Much confusion existed as to its value in fevers because no accurate differentiation could be made, at that time, between fevers due to malaria and those due to all other causes, in most or all of which cinchona has little or no effect. Notwithstanding this confusion and other disadvantages, the beneficial effect was so definite and convincing that its use spread, rapidly for those times, throughout the civilized world where malaria prevailed. Torti, in 1753, divided fevers into those that are cured by the bark and those that are not. We now know that this was a somewhat inaccurate, but at that time the best available, method of differentiating malarial fevers from fevers due to other causes.

The isolation of quinine from cinchona bark by Pelletier and Coventou, in 1820, marked another advance in the treatment of malaria. This has proved to be the most effective against malaria of any of the alkaloids of cinchona. Greater accuracy in dosage was a most important advantage of quinine over "the bark." Because of this and other advantages, quinine has been the alkaloid generally used for malaria up to this time.

Later the discovery of the malaria parasite by Laveran, in 1880, made accurate diagnosis possible and also made it possible to evaluate quinine in malaria by observing its effect on the parasites, in addition to its effect on the clinical course of the disease. To this day cinchona first and later quinine has remained the sovereign remedy for malaria the world over.

The widest range of dosage and methods of administration is practiced. This leads to great variation in the results from its use. However, it has such a definite specific effect in malaria that more or less benefit results from its use in almost any way. The fact that good results are obtained from such a wide range of dosage and methods of administration explains why there are so many different methods of treatment advocated. There are almost as many methods of treating malaria with quinine as there are authorities on the subject. Most of them are good; all have some effect, depending chiefly on the amount of the drug used and the duration of the treatment.

Quinine is so specific in malaria that I believe it can be correctly said that all cases can be relieved of clinical symptoms and finally cured of the infection with sufficient doses for a sufficient length of time, with the possible exception of severe cases in which too great damage has already occurred before the effect of the remedy can be obtained. Such cases are extremely rare. They are so rare as to permit an authority with the large experience of Major J. A. Sinton[1] to say only recently that among more than 1,500 patients suffering from benign tertian malaria he has not found a single case of quinine resistance, although many of them arrived with histories of having this condition; nor did he see relapses occur during the course of quinine treatment.

Quinine as a remedy for malaria has its drawbacks and objectionable features notwithstanding the fact that it is practically 100 per cent effective. Among the more important objections are more or less discomfort which adequate therapeutic doses cause in a good many persons; great variation in its general effect and in its antimalarial effect in different individuals, necessitating unnecessarily large doses in many; and the length of time required to cure the infection in many cases, necessitating unnecessarily long treatment in many. The latter would not be so bad if it were not for the fact that there is no method now known whereby the length of treatment that will be required to cure the infection in any given case can be determined in advance. In one case only a few days of quinine treatment may be sufficient, in another a month or two may be necessary, and in still another even as long as three months of continuous quinine treatment may be necessary.

To make it still worse, there is no method of examination that will tell whether the patient is cured of his infection or not. The fact that all clinical symptoms stop means nothing in this regard; neither does a negative blood examination. A patient who has been under treatment may have no clinical symptoms whatever, and his blood may be negative for malaria parasites, and still he may relapse within from a few days

* Read before the Section on Practice of Medicine at the Eighty-First Annual Session of the American Medical Association, Detroit, June 27, 1930.

[1] Sinton, J. A.: Far East. A. Trop. Med., Tr. Seventh Cong., 1927, 2: 599-867, 1928.

to a few weeks or months with typical symptoms and many parasites in his blood.

Since there is no way of telling in advance the length of treatment that will be required in any given case to cure the infection entirely or of telling when this result has been accomplished, it is necessary to give to all patients quinine treatment over a sufficiently long period of time to cure a high percentage of cases. There is great difference of opinion as to the proper length of time. Eight weeks of continuous quinine treatment is considered by many as the proper length of treatment for routine cases. This cures the infection in almost 100 per cent of cases of the estivo-autumnal type and perhaps less than 90 per cent of the tertian and the quartan type.

There have been literally hundreds of remedies besides quinine advocated and promoted for malaria. It would be far beyond the scope of this paper even to attempt to list them. At one time or another most of the drugs used in the treatment of other diseases have been advocated for malaria, in many instances followed at first by enthusiastic endorsement.

Much of the erroneous belief in worthless remedies for malaria has resulted from overenthusiastic, inaccurate observations, associated especially with inaccurate diagnosis. A certain diagnosis of malaria cannot be made except on the presence of malaria plasmodia in the blood. Sometimes the blood examination, if made, is trusted to incompetent technicians or to others whose diagnoses are relied on in evaluating the new remedy under consideration. Most of the endorsement and advocacy of worthless remedies for malaria, however, are based on inaccurate diagnosis of cases without blood examination. While large experience may enable one to guess the diagnosis of malaria correctly in many cases, such guesswork by the best of guessers is not correct frequently enough to serve as a basis for judging the antimalarial value of unproved remedies.

Notwithstanding the enthusiasm with which many different remedies besides quinine have been advocated from time to time, all of them have gone the same way, into disuse, with the exception of certain new ones which have not been in use long enough to see what their outcome will be. I will refer briefly to two of these belonging to the arsenical group and, somewhat more at length, to an interesting new remedy, plasmochin, first introduced in 1926.

VALUE OF ARSENICALS

Arsenic in different forms has been used for malaria for a long time, usually in combination with quinine, the great importance of which was overlooked or underestimated in evaluating the arsenic. The long duration of the opinion that arsenic in one form or another has some beneficial effect on malaria would make it seem highly probable that there is some basis for the belief. Solution of potassium arsenite has long been used, as have also other forms, usually combined with quinine. Although perhaps one cannot say that arsenic in these forms has no effect, it can be said that what little effect it may have is insignificant as compared with that of quinine.

More recently arsphenamine and neoarsphenamine have been used quite extensively in some localities. Central American physicians use it more than others. The use of these preparations as remedies for malaria seems to be more closely related to the appeal for intravenous therapy than to the cure of malaria. The very fact that they are given intravenously gives them a strong appeal to patients and, I am sorry to say, to many physicians.

Intravenous administration of fluids of almost any kind has some beneficial effect in malaria and it is hard to tell whether the slight effect from arsphenamine and neoarsphenamine is due to the arsenical or merely to the damage to the blood by the intravenous fluid. Any fluid, even salt solution, given directly into the blood stream damages the blood cells to some extent and tends to make them an unfavorable soil for the malaria parasites to grow in. The addition of even small quantities of salt solution to blood in the test tube affects it in such a way that malaria parasites will not grow but soon die in it. If, on the other hand, to such blood a little dextrose but no salt solution is added, malaria parasites live and grow in it. However, the beneficial effect of arsphenamine and neoarsphenamine resulting from intravenous administration (and not from any specific action) is so slight and so variable and this method of treatment of malaria is so unnecessary that it is rapidly growing into disuse. It cannot be denied, however, that, when violent reactions are produced by intravenous medication with arsphenamine or other drugs and sufficient damage is done to the blood, malaria parasites are damaged also, and, in fact, sometimes, although rarely, complete cure results.

Acetarsone, another arsenical given either intravenously or orally, has had a rather extensive trial in malaria. Of all the newer arsenicals, perhaps this one stands out above all others for variation in the susceptibility of different individuals to its toxic effect. One individual shows little or no harmful effect of full doses and another is greatly harmed or even killed by much smaller doses. The violent reactions that occur in many cases cannot be foretold, and the symptoms produced by the inevitable injury to the liver are especially indefinite. They do, however, tend to benefit malaria by making the blood cells unfavorable soil for the malaria parasites to live and grow in. But danger and harm produced by acetarsone, in addition to the fact that its antimalarial effect is negligible as compared with that of quinine, have prevented extensive use of it. It is a fact, however, that malaria no doubt may sometimes be cured with acetarsone. There is no likelihood that its use will increase.

Sinton,[2] in a careful observation of twenty-five cases of chronic benign tertian malaria treated with acetarsone and after reviewing the work of others last year, concluded that the intravenous injection of sodium acetarsone in varying doses up to a total of 4 Gm. in five days has produced a true cure in only a small percentage of cases and has not confirmed the encouraging results claimed by other workers in this respect. However, intravenous injection of 1 Gm. of sodium acetarsone will cause the disappearance of *Plasmodium vivax* from the peripheral blood and a clinical cure in the majority of cases.

TREATMENT WITH PLASMOCHIN

A more interesting "specific remedy" for malaria, plasmochin, was promoted by Muehlens[3] first in 1926. Plasmochin is a synthetic derivative of quinoline and is somewhat indefinitely stated to be an alkyl-amino-6-methoxyquinoline salt. The resemblance of its chemical formula to that of the quinine group suggested the possibility of its having an effect in malaria. It was first tried on bird malaria by Roehl.[4] Doses of 1 cc. of a 1 : 50,000 solution for each 20 Gm. of body weight were found to prolong definitely the incubation period of malaria following inoculation in birds.

[3] Muehlens, P.: Treatment of Natural Malaria with Plasmochin, Arch. f. Schiffs- u. Tropen-Hyg. supp. **20**: 325-335, 1926.

Muehlens[3] reported that rapid abatement of symptoms and disappearance of parasites occurred in tertian malaria but that in the subtertian form the effect was less marked on symptoms and asexual parasites. However, the number of gametes rapidly declined and all soon disappeared. This claim of selective action against gametes, especially crescents, sounded a receptive note and greatly increased interest in this new drug. Emphasis has been laid on it by most of the large number of enthusiastic endorsers of the remedy ever since. They sometimes seem to fail to realize that crescents ever disappeared before without plasmochin. No new remedy for malaria has ever been so successfully promoted, so widely used or so enthusiastically endorsed in so short a time. While adverse reports have appeared from time to time, the favorable reports are much more numerous. Although it is only a little more than three years since plasmochin was first introduced, there is already a voluminous literature on its use, consisting largely of clinical reports and observations.

Soon after its first introduction it was apparent that, although plasmochin alone would give clinical cures of simple tertian malaria, it had little effect on estivo-autumnal malaria except for the claim that it had some mysterious specific ability to destroy crescents. The situation was happily met by combining quinine with the plasmochin in the form of so-called plasmochin compound, now put out in the form of tablets containing 0.01 Gm. of plasmochin and 0.125 Gm. of quinine sulphate. The directions in the latest circular of the manufacturers advise giving two tablets three times daily. This corresponds to 0.75 Gm., or about 12 grains, of quinine daily. Practically all plasmochin used in clinical tests for the last year or two has consisted of this combination with quinine. The results are bound to be good in most cases for they would be from the same amount of quinine without the plasmochin. There is a tendency to lose sight of the quinine and to attribute the results to plasmochin. As a matter of fact, corresponding results are produced by the same amount of quinine without the plasmochin. But the very fact that clinical and parasitic cures are obtained from plasmochin alone in some cases of tertian malaria would justify the belief that the antimalarial effect of the two drugs combined may be somewhat greater than that of either alone in this type of malaria and possibly in others. However, it is difficult to measure this increased effect for the reason that few or no cases of tertian malaria can be found in which 12 grains of quinine daily does not promptly control the clinical symptoms. The effect of plasmochin compound in malaria should not be attributed to plasmochin primarily. To the quinine should be attributed such effect as results from quinine without the plasmochin. If this correct line of evaluation is followed, there will not be so much effect left for the plasmochin.

Plasmochin has a high toxicity and this seems to vary greatly in different individuals. The toxic symptoms that have been noted consist chiefly of cyanosis, pallor, nausea, gastric pain and distress, headache, dizziness, epistaxis, hemoglobinuria and weakness. Such unforseeable individual results and sometimes grave symptoms may arise without warning. Brosius[5] reported ten, or 16⅔ per cent, of sixty patients taking as much as 0.06 Gm. daily as suffering from cyanosis, hemoglobinuria, nausea, headache or relapse. Two deaths occurred in about 200 patients treated, in neither of which did the autopsy reports absolve plasmochin from blame, if not from being the definite cause.

In this report, other members of the medical staff of the United Fruit Company reported their experiences with plasmochin. Cordes[6] says: "In occasional cases without previous warning very grave symptoms arise. It is only since we have used plasmochin that these accidents have repeatedly occurred with striking similarity." Phelps,[7] who had some undesirable reactions in eleven of nineteen cases, stated it as his belief that "it is a dangerous drug with unforseeable individual results." Macphail,[8] on the other hand, from his experience with a considerable number of cases, considered it safe under very ordinary supervision.

In a group of eighty-six patients given plasmochin, either with or without quinine, in doses of 0.08 Gm. daily, Sinton and Bird[9] found it necessary to discontinue the treatment on account of toxicity in five cases. A 71 per cent relapse rate occurred in a group of fourteen patients with tertian malaria who were given plasmochin alone or plasmochin compound against a 14 per cent relapse rate in a group of seven patients given quinine and alkali.

The blood of patients with severe toxic symptoms is chocolate colored, and methemoglobinemia, as well as methemoglobinuria, is always present. In fact, methemoglobinemia is produced although no toxic symptoms are recognized. This occurs both in experimental animals and in man in practically 100 per cent of cases.

Fischer and Weise[10] made an extensive study of the cause of the cyanosis in plasmochin poisoning and found that methemoglobin could always be detected in the blood of twenty-five out of twenty-six patients within a few days after the commencement of treatment, while treatment was continued and for some time afterward. The intensity and duration increased with prolonged administration.

As has been pointed out, anything that damages the blood sufficiently makes the blood cells an unfavorable soil for malaria plasmodia to live and grow in and thereby tends to benefit malaria. The methemoglobinemia practically always produced by therapeutic doses of plasmochin would offer a plausible explanation for the limited effect thus far demonstrated for this drug. However, there may be considerable question whether such blood damage, even to the extent of producing chocolate colored blood in some cases, can be justified in view of the well known less effectiveness of the drug on clinical malaria than that of quinine. Final conclusion as to the justification of its use must await still further knowledge and experience as to the extent of the harm it does and the advantages to be derived from it.

ACTION OF PLASMOCHIN ON GAMETES

Now comes the most remarkable of all claims and experiences with plasmochin. One of the claims that has been put forth for plasmochin from its first introduction is that it has some selective and destructive action against the gametes of all kinds of malaria, but especially the crescents of *Plasmodium falciparum*; this in spite of the fact that the effect on the asexual forms of this parasite is so limited as to necessitate the use of quinine to control clinical symptoms. It is possible that many such statements and claims are merely the repetition of similar claims made by others and in many instances not based on carefully controlled observations.

Several apparently competent observers claim that they have found some alteration of the staining qualities or other changes in the appearance of the parasites. Others have not been able to confirm such observations. Only time and further accurate studies can tell whether this is the case or not.

Barber, Komp and Newman[11] fed susceptible mosquitoes on patients at various periods following the administration of plasmochin. The infectiveness of these patients to mosquitoes before plasmochin was given was proved by feeding and subsequent dissection of the mosquitoes. Only patients proved in this way to be capable of infecting mosquitoes were used for the plasmochin experiments. In three such subjects who were available, administration of plasmochin was followed by failure to infect. This result is the more remarkable in view of the fact that the gametes in some of the cases following plasmochin were observed to be alive and, in fact, exflagellation was also observed. Still more remarkable was the observation that in one case apparently the gametes were made impotent within a few hours by an infinitesimal dose of 0.5 centigram of plasmochin. This is a dose only about 1/140,000,000 of the body weight. Such selectivity is so rare, if it has ever occurred before, that it will be necessary for this work to be confirmed in a larger number of cases before it can be accepted as conclusive, notwithstanding the care the authors exercised for accuracy.

Deeks[12] states that these results have been confirmed to a considerable extent at least by Colonel Eugene Whitmore. He found that the administration of 1 centigram of plasmochin did not always prevent oocysts from developing in the mosquitoes, but that they were fewer in numbers. Furthermore, in no instance were mosquitoes infected that had fed on patients who were given 2 centigrams of plasmochin.

SUMMARY

1. Cinchona alkaloids, especially quinine, constitute the only specific remedy for malaria.

2. Arsphenamine, neoarsphenamine and acetarsone have some nonspecific effect, as do many other drugs, but such effects are so far inferior to that of quinine that their use is on the decline.

3. Plasmochin has a definite effect on clinical malaria and both clinical and parasitic cures may be accomplished with it alone. Plasmochin has far less effect on malaria than has quinine, and its toxicity, which is associated with methemoglobinemia, makes its routine use questionable.

4. Evidence has been brought forth by others that plasmochin has some specific action on the reproductive power of gametes. These observations are of great importance, if correct, and need further confirmation.

1551 Canal Street.

ABSTRACT OF DISCUSSION

Dr. L. L. Williams, Jr., Richmond, Va.: To those primarily interested in the cure of malaria it is comforting when so close a student of malaria iterates the curative value of quinine and relegates to their proper places many of these latter day medicines, which, although somewhat beneficial, are not nearly so much so as quinine. Dr. Bass again performs a real service in emphasizing the superiority of the oral method of administration of quinine and in stressing the importance of giving the patient quinine in a form that may be easily retained and assimilated.

Dr. Bass has picked out the true value of plasmochin and has given it its proper place in treatment. Alone it will cure cases of benign tertian malaria. When used in conjunction with quinine in cases of benign tertian malaria the relapse rate is much less than when quinine alone or plasmochin alone is used. In malignant tertian malaria, however, plasmochin has no effect on the clinical course. In the proper treatment of malaria it is essential in the best interests of the patient that an accurate diagnosis be made of the type of malaria. Various workers studying the malarial paroxysm in the malignant tertian form found a considerable lessening of the alkali reserve of the body.

Sinton's experience showed that after only 110 grains (7 Gm.) of quinine with magnesium sulphate the cure rate was 60 per cent, and that when alkali was added the cure rate rose to 72 per cent. In another series of 237 cases without alkali the relapse rate was 72 per cent, whereas 281 cases treated at the same time with the addition of alkali showed a relapse rate of only 35 per cent.

The development of plasmochin and quinine for benign tertian, and alkali and quinine for malignant tertian malaria, with a possible public health benefit from the action of plasmochin on gametocytes, is the greatest advance in malarial therapy since the isolation of the alkaloid from cinchona bark.

Dr. Allen H. Bunce, Atlanta, Ga.: Quinine is a safe drug. It cures malaria. It may be given to the most ignorant patient with little or no supervision. Plasmochin is a dangerous drug and should never be given except under the closest supervision. In the two cases of plasmochin poisoning which I have studied, one of which proved to be fatal, in addition to the symptoms mentioned by Dr. Bass I found a hypoglycemia. This hypoglycemia suggests a method of treatment of plasmochin poisoning which will surely occur if plasmochin is used. I see no reason for giving up a safe, dependable treatment for malaria for something that is dangerous, except when patients can be kept under close observation.

Dr. C. D. Pillsbury, Washington, D. C.: Three or four years ago I had the experience of conducting the pediatric service at Gorgas Hospital in the Canal Zone, in which institution of course there is a large incidence of malaria, of both the tertian and the estivo-autumnal type. Plasmochin was introduced, as Dr. Bass has said, about 1926, but did not reach the Canal Zone for use in malaria until about a year and a half to two years later. We did not regard it as being worthy of routine use by any means, but in view of the fact that a large number of our patients were from the families of colored employees of the canal, and the economic factor entered decidedly in the prolongation of hospitalization (requiring as we did three negative blood smears before the patient could be discharged), and as we found that in the case of estivo-autumnal malaria many of these children showed crescents persistently over a long period, in an attempt to shorten the period of hospitalization we began to use plasmochin in these selected cases, though always with the continuation of the quinine treatment. Our experience was necessarily limited because only a relatively few cases were resistant, that is, showed the persistence of the crescents over a period of ten days to two weeks after the temperature had been normal. In these cases, however, there did seem to be some benefit to be derived from the use of plasmochin, in that the crescents rather rapidly disappeared from the peripheral blood. In one case we withdrew the plasmochin as soon as the first negative blood smear was obtained and in a day or two later the crescents reappeared. Plasmochin was resumed, the crescents did not reappear, and the patient was discharged. This represents only a few cases, but my impression was that plasmochin was of some value in the control of crescents in estivo-autumnal malaria.

[12] Deeks, W. E.: Recent Developments in the Control of Malaria, South. M. J. **23**: 417-420 (May) 1930.

Dr. C. C. Bass, New Orleans: The experience of Dr. Bunce, that there is a hypoglycemia, would be expected, I presume, from the serious damage that is done also to the liver. In all autopsies on plasmochin poison cases, the liver and the kidney are damaged. I am advised by biochemists that exactly this effect should result from aniline and aniline derivatives of almost any kind. I do not want to be misunderstood as claiming that plasmochin does not have any effect in malaria. I am sure that malaria can be cured with plasmochin as with many other things, but the question I think would naturally arise at the present time as to whether the price paid is worth the results.

ORTHOPEDIC ASPECTS OF CHRONIC RHEUMATISM OR ARTHRITIS *

ROBERT BAYLEY OSGOOD, M.D.
BOSTON

It is perhaps fitting that I should offer some explanation, if not a defense, of the invasion of a general medical field by a surgical specialty. The purpose of the invasion was to help defeat a strongly intrenching enemy of health whose ally seemed to orthopedic surgeons to be the lethargy of the general practitioner toward the importance of the problem of chronic arthritis and toward its solution.

Orthopedic surgeons were faced originally by the widespread deformities of the joints that were associated with the active disease and that persisted as fixed crippling deformities after the fires of active disease had burned themselves out. They have become aware of the generalized nature of the disease, of the frequent failures to relieve completely or even to influence materially the course of the disease by the surgical removal of supposed bacterial foci of infection, and of the contrasting successes of treatment planned along general lines of physical and mental rehabilitation and an appropriate dietary and eliminative regimen. The orthopedic surgeon has been the last resort rather than the first resort, and this fortunate attitude of the public, by enabling him to see the pitiful end-results, has stimulated him to attempt by any means he could devise to prevent these deformities and to recognize the prodromes of the disease. My defense is ended and I hope you will look on me as an ally in a common cause, ready to be told to return to my own particular business when our common enemy is evidently facing defeat.

CLASSIFICATION

Orthopedic surgeons dealing with acute and advanced cases of chronic arthritis have been conscious of two very different forms of the disease. These different types were evident and were characteristic at the onset, during the course and in all but the very terminal lesions of the disease. They show a different age incidence, a different anthropological body type incidence. The earliest microscopic and macroscopic changes in joint tissue are different and these changes continue to be characteristic throughout the course of an unchecked disease. Clinical investigators, pathologists and the patients themselves have all recognized the two main types. It may be possible, with increasing knowledge, to subdivide these two types many times. For the moment, a simple working classification and general recognition of at least two types is desirable, for their prodromal signs and symptoms are different, their local joint changes are different and it would seem as if the medical treatment of the two types should, in some respects at least, be different. The orthopedic treatment of the joint lesions themselves in the two types differs essentially. I shall call them the atrophic and hypertrophic types, because this terminology is perhaps most commonly employed in current American medical literature. It seems to be more differentially descriptive and more easily understood than the British terminology of rheumatoid arthritis and ostearthritis. It is the nomenclature that has been adopted by the American Committee for the Control of Rheumatism.

The first type is called atrophic, because, although the earliest pathologic change is proliferation of the synovial membrane, which one may only guess at in the roentgenogram, there is also a very early diminution in the density of the bone ends which can be appreciated as atrophy in the roentgenogram and soon as actual loss of substance; there is an early atrophy of the muscles controlling motion of the joints; and the disease is much more common in the slender, asthenic, atrophic type of person. The age incidence is from birth to middle life.

The second type is called hypertrophic, because, although the primary change may be a fibrillation of the articular cartilage that cannot be detected in the roentgenogram, there is almost simultaneous lime salt deposit in the form of chondro-osseous spicules and ridges at the articular margins, which is easily visible in the roentgenogram; there is no appreciable atrophy either of the bone ends or of the muscles controlling motion of the joints until very late; and the disease is perhaps more common in the stocky, sthenic, well nourished hypertrophic type of person who tends to an overdeposit of calcium in his tissues. Its age incidence is from middle life to death. As the disease progresses, in each type these characteristic changes become more striking in the roentgenograms, to the eye, when the joints are opened and in microscopic sections of tissue. The gross pathologic changes and the microscopic changes are consistent.

[Lantern slides were shown illustrating the following characteristics of the two types:]

A. In the atrophic type:
    1. Proliferation of the synovial membrane.
    2. Thinning and loss of calcium from the trabeculae of the bone ends; much fat.
    3. Erosion and imprisonment of articular cartilage; pannus formation.
    4. Loss of substance of bone ends and bony ankylosis.

B. In the hypertrophic type:
    1. Early delicate spicules forming at the articular margins, with no diminution of the density of the bone shadows and no evident change in the articular cartilage.
    2. Increase in the chondro-osseous hypertrophic overgrowths of the bone ends, with changes in the articular cartilage.
    3. The formation of joint mice, which is common.

---

* Read before the Section on Practice of Medicine at the Eighty-First Annual Session of the American Medical Association, Detroit, June 25, 1930.

4. Dense trabeculation at bone end, in contrast with atrophic type.
5. Final loss of articular cartilage and eburnation of the bone beneath; deformation of bone end, but no bony ankylosis. Malum coxae senilis.

ORTHOPEDIC ASPECTS

In what ways may the orthopedic surgeon be useful in helping to control the types of diseases included under the term chronic arthritis? First, along with the rest of the medical profession by becoming aware of the wide incidence of the disease; second, by recognizing the prodromal signs and symptoms of the generalized disease; third, by helping to prevent deformity in the active stages; fourth, by restoring function by means of appliances and surgery when the disease has become quiescent.

Differences in Incidence, Onset, Signs and Symptoms, Roentgenologic Appearances and Morbid Histology in the Two Main Types of Chronic Arthritis Designated as Atrophic Arthritis and Hypertrophic Arthritis

	Atrophic Arthritis	Hypertrophic Arthritis
Common synonymous terms used in other classifications	Still's disease; rheumatoid arthritis; proliferative or ankylosing; arthritis deformans; spondylitis; Mabie-Strümpell syndrome	Ostearthritis; degenerative or nonankylosing arthritis; menopause arthritis; ostearthritis of the spine, von Bechterew syndrome
Incidence:		
Age	From infancy to middle age	From middle age till death
Body type	More common in slender, ptotic women	More common in stocky, well nourished men and women
Onset	Acute to insidious	Subacute to ignorance of presence
Symptoms and signs	General health usually not robust; pain and disability often pronounced; joint swellings and muscle atrophy to be observed	General health usually excellent; pain and disability usually slight; joint swellings and muscle atrophy rarely noticeable
Roentgenologic Appearances:		
Early	No apparent cartilage or bone changes; generally, increased density of soft parts of joint	Slight "lipping" of articular margins; no general increased density of soft parts of joint
Late	Diminished density or bone atrophy; narrowed articular space; subluxation and ankylosis	Unless through long nonuse, no diminished density of bone; articular space irregular; hyperostoses; no ankylosis
Morbid histology:		
Early	Early proliferation of synovial membrane; pannus; usually small round cell infiltration	Early fibrillation of articular cartilage; no general proliferation of synovial membrane or small round cell infiltration; chondro-osseous hypertrophy of articular margins; joint mice
Late	Late destructive and atrophic processes in cartilage and bone; fibrous or bony ankylosis	Eburnation, deformation and hypertrophy of articular bone ends; cyst-like cavities in cancellous bone near the articular surface; no true bony ankylosis

Prodromal Stage.—Rheumatism is said to run in families. Physicians have been impressed with the strong hereditary tendencies of chronic arthritis.

Atrophic arthritis is much more common in the young, thin, ptotic type of person. Women are more susceptible than men. The "set up" is inefficient. Their muscles are poor, their thoracic cages are narrowed, their diaphragmatic excursion is small, their abdominal viscera are sagged, the weight bearing lines of their joints are not true, muscle tonus is hard to maintain because the center of gravity is disturbed. They are fatigued. Their body mechanics is wretched. If bad body mechanics can be converted into good body mechanics; if inefficient "set ups" can be changed into efficient ones by positional rest periods, exercises and temporary supports; if more room can be provided in the thoracic cage for heart and lung action; if the diaphragmatic pump can be set working again on the abdominal veins and viscera; if their symptomatic joints can have their normal weight bearing thrusts restored; then there would seem to be inevitably less wear and tear, a higher circulatory coefficient, more nearly normal alimentation, less fatigue and a better chance for the defense mechanisms of the body to overcome whatever bacterial or chemical toxins are being elaborated, which presumably are or will be responsible for the symptoms in the joints.

With the cooperation of the patient and by the intelligent, patient effort of his physician, the skeletal structures and the relation of the viscera in both adults and children may be remodeled to a surprising extent.[1]

In hypertrophic arthritis, the same principles of improving faulty body mechanics obtain. With its older age incidence, the remodeling of the body is harder but, fortunately, there is usually less remodeling to be done. Supports are easier to apply and are more gratefully received. Fixation and protection relieve symptoms enormously. They may be applied without danger of interfering with the motion of the joints, and in the early stages are often only a temporary or intermittent necessity.

As Pemberton and Peirce have shown, there seems to be a deficient blood supply to arthritic joints. In the early stages of the disease when there may be no joint signs and only intermittent joint symptoms, increasing the local blood supply to joints by heat, massage, voluntary exercise and general physical therapy may well restrain, if not prevent, permanent changes of tissue in the joints.

It is, of course, to be understood that at this stage all possible true bacterial foci are being overcome, the balance between physical and mental outgo and intake is being restored, and all dietary surfeits or deficiencies are being corrected and elimination assured. These measures and others come within the purview of the internist.

I am eager, however, to interest the general profession in this matter of body mechanics. There is evidence to suggest that the association of poor body mechanics and poor health is not incidental but is potentially important, and that good body mechanics stands in a partly causal relation to good health. It seems to orthopedic surgeons that the attainment and maintenance of good body mechanics should be a sine qua non in the treatment of all forms of chronic arthritis.

Prevention of Deformity and Maintenance of Joint Motion.—To army medical officers it is hardly necessary to emphasize the importance of avoiding preventable deformity. The methods of prevention are simple; they include traction and the intermittent use of splints and appliances and of voluntary motion of the joints. If a joint threatens to become permanently stiff in spite of treatment, the optimum functional positions of ankylosis must be constantly kept in mind. A straight stiff elbow is vastly more useless than a right angle stiff elbow. We are not horses but men, and equinus of the foot is awkward. Knees left flexed more than 25 degrees throw all the other weight-bearing joints out of true.

Local Treatment of Joints.—The primary object of local treatment of the affected joints should be to increase their blood supply. Heat in its various forms of application, massage, and voluntary exercise, stopping short, of course, of irritation of the joints; in other words, intelligent physical therapy, often attended by its useful handmaiden occupational therapy, relieves pain and improves function.

---

[1] The methods for accomplishing this are described in a little book entitled "Body Mechanics and Health," by Miss Leah C. Thomas, Boston, Houghton Mifflin Company, 1929.

Sensitive weight-bearing atrophic joints tending to contractures may with advantage be supported by light apparatus in order to allow painless and nonirritating functional use so important in combating the atrophy of nonuse. A word of caution may be given here concerning too complete and too continuous fixation of joints in the atrophic type. Adhesions are prone to occur and atrophy increases very rapidly. A little pain is the lesser evil.

Protection by apparatus to sensitive hypertrophic joints is always grateful to patients and often relieves them of all discomfort. There is no danger of ankylosis in even completely fixing these joints for several days. There is less fear of producing atrophic changes in the bone.

There is no specific drug or vaccine for all cases of either type. There are many different drugs which are useful and appropriate for different cases and at different stages of the disease. The correction of actual endocrine deficiencies sometimes strikingly relieves arthritic symptoms. The orthopedic surgeon sits at the feet of the internist in respect of drugs.

Surgery.—Thus far, it seems as if the orthopedic aspects of chronic arthritis which I have mentioned ought to be, or to become, medical aspects as well. These measures are not orthopedic measures; they *should be the measures of general medicine.* Surgery, narrow as its field is in chronic arthritis, may perhaps be looked on as an orthopedic aspect until orthopedic surgery is again absorbed by general surgery, which should be its desired goal.

The surgery of chronic arthritis is patchwork surgery. Little is to be hoped from surgery while the disease is active. Perhaps the aspiration of a tense atrophic joint, perhaps the removal of an impinging hypertrophic spur, with no guarantee of its nonrecurrence if the disease is active; perhaps the removal of an incapacitating joint mouse.

When the disease has been arrested, surgery may restore large amounts of function. If an incapacitating proliferation of the synovial membrane persists, the whole membrane may be excised and it will regenerate as well as repair. Division of adhesions in the joints and contractures of muscles and joint capsules may improve motion and make possible good weight-bearing lines. Reconstruction operations, occasional formal and informal arthroplasties to restore motion, occasional arthrodeses to stop pain, in joints whose remaining few degrees of motion are a menace rather than a blessing: these are the main conrtibutions of surgery to the relief of chronic arthritis and, from the point of view of the patient who needs them, are great contributions. Let us remind ourselves, however, that in general they are necessary only when the patient's medical advisers have not been sufficiently alert or the patient has sought informed advice too late.

Every one will admit that chronic disease is the most important health problem of the present day as it has been through the centuries, but that too little attention is paid to it. Chronic rheumatism is the most widespread of the chronic diseases and both socially and economically the most important. In a recent house to house survey of two widely separated communities in the state of Massachusetts, each including both urban and rural inhabitants, fair samples of the whole state, chronic rheumatism was twice as common as heart disease, six times as common as tuberculosis and fifteen times as common as cancer. The European figures gathered by the International Committee for the Study of Rheumatism are quite as striking. The American Committee for the Control of Rheumatism, a branch of the international association, at its 1929 October meeting unanimously agreed on a concept of the disease. It is short and inconclusive but to my mind marks an epoch in the control of chronic arthritis because it means that internists and surgeons and research workers have been able to agree as to the probable nature of the disease and as to lines along which efforts for its control should be directed.

CONCEPT OF THE AMERICAN COMMITTEE FOR THE CONTROL OF RHEUMATISM CONCERNING THE DISEASE COMMONLY CALLED CHRONIC RHEUMATISM OR ARTHRITIS

1. The disease chronic arthritis, prevalent in all temperate zones, represents one of the most important, if not the most important, of existing social and industrial handicaps.

2. The committee conceives of the disease as a generalized disease with joint manifestations. Certain prodromes may be recognized. It is of vital importance that they be recognized.

3. It is the opinion of the committee that at the present time no single infectious agent or any completely defined dietary deficiency or metabolic disturbance has been conclusively shown to be the sole cause of these disorders. The committee inclines to the belief that any one of these factors or certain combinations of these factors under appropriate circumstances may basically underlie the onset of the disease.

4. The committee feels it of vital importance that the medical profession have its attention directed to the methods of proved value which are at present at its disposal. In spite of etiologic uncertainties, the committee feels that properly managed therapy which takes into account both infectious and metabolic factors has yielded results which encourage optimism and impose the obligation of further developing such methods.

5. In the light of the foregoing considerations the committee purposes to broadcast as widely as possible both to the profession and to the public its concept of the nature of the types of arthritis included under the heading chronic rheumatism, its belief as to the probable predisposing and exciting causes of the disease, and the knowledge which the committee possesses or may acquire as to the most efficient methods of treatment.

CONCLUSION

I have been suggesting that there may be an orthopedic aspect to chronic arthritis; perhaps the relation of orthopedic surgeons to internists is slightly analogous to that of the physicists to the astronomers. As Professor Douglas reflects, "The riddles of the stars cannot be solved without involving the aid of the atoms, nor can the atom be comprehended without the aid of the stars." You internists are the stars. The orthopedic surgeon may be the atom.

372 Marlborough Street.

ABSTRACT OF DISCUSSION

Dr. Ralph Pemberton, Philadelphia: In the last analysis, the group in medicine which has known much about this topic, because of having to be interested in it, is the group represented by orthopedic surgery. While Dr. Osgood was too polite to say so, he knows that orthopedists got their experience in large part because of the errors which we internists have committed. The study made by Nichols and Richardson twenty or thirty years ago was really made possible because of the interest which Dr. Osgood and a few of his confrères had in arthritis. Probably only a few here realize the degree to which circulatory dynamics play a part in this problem. Those who have followed the work of Bock and his colleagues, based on the work of Haldane and other English physiologists, know that in any healthy individual the efficiency of the heart output may be reduced 50 per cent or more in changing from the recumbent to the erect posture. Think what that means in terms of the individual whose body mechanics and therefore whose circulatory mechanics is not correct. The evidence is strong today that at least part of the pathology of arthritis is referable to disturbance in the finer vascular blood supply. Dr. Osgood has helped us to understand that arthritis is a systemic disease; that it has prodromes; that the joint manifestations are only local expressions of the systemic disturbance and that this process may manifest itself elsewhere. Arthritis, as Charcot pointed out fifty or seventy-five years ago, is simply a branch of a great pathologic tree. We talk about "arthritis" because the joint symptoms are the most conspicuous and not because they constitute the whole story. One of the fine things that Dr. Osgood has done has been to introduce criteria of a stable nature in this field. There are many more needed, to be sure, but these questions of classification, the relation of the body mechanics, the condition of the viscera, and the question of the circulation as a whole are of fundamental importance. There is no justification today for any thoughtful physician to feel at sea in this disease. The amount of useful data available to any one who wants to inquire into the disease is large. It is the feeling of many of the American Committee for the Control of Rheumatism that there are few chronic diseases for which more can be done.

DR. RUSSELL L. CECIL, New York: Dr. Osgood has stressed the differentiation of chronic arthritis into two groups. I should like to suggest some differences in their etiology. The atrophic type—Dr. Osgood has referred to the inflammatory change that occurs in the joint, the so-called pannus, which is nothing more than granulation tissue, similar to that seen in any other inflammatory focus. This granulation tissue can readily be duplicated in rabbits injected intravenously with streptococci. They develop an experimental arthritis which goes to a chronic form and histologically the lesions produced in the rabbit are identical with those seen in man with the atrophic type of arthritis. On the other hand, the hypertrophic type of arthritis cannot be produced experimentally by bacteria. Bony changes may occur late in the disease just as they do in man, but a true hypertrophic arthritis is not produced in that way. It can be produced, however, by exciting trauma in the joint, for example, by putting a foreign body into the rabbit's joint. This rather indicates that atrophic arthritis is an infectious process and that the hypertrophic arthritis is bound up in some way with trauma or wearing out of the joint. In the laboratories at Bellevue Hospital, we have never been successful in getting bacteria of any kind from the hypertrophic joint. This also bears out the theory that atrophic arthritis is an infection, and that hypertrophic arthritis is a degenerative process. Furthermore, in recent studies not yet published we have found that the blood of patients with atrophic arthritis shows high agglutinins for arthritic streptococci, while these agglutinins are absent from the blood of patients with hypertrophic arthritis. Thus more and more evidence is accumulating that these two types of arthritis, both of which produce pain and discomfort and loss of function in the joint, are perhaps entirely different processes. The importance of this point of view is great from the standpoint of treatment. It means that in the atrophic type one's first efforts should be directed to removing all foci of infection and then one should proceed to build up the patient in a constitutional way, whereas in the hypertrophic type one is perhaps not so eager to remove foci but will direct attention to resting the joint, relieving strain, and giving the joint support of various kinds.

DR. W. PAUL HOLBROOK, Tucson, Ariz.: Out of a series of about 200 carefully studied patients with chronic arthritis in the past year more than half had definitely preventable deformities, had they had attention earlier.

DR. ROBERT B. OSGOOD, Boston: If these cases are treated early, the orthopedic surgeon will not have any cases to treat. The orthopedic surgeon is at present faced with this situation: he sits in his office and sees patients come in without teeth, without tonsils, without every known or unknown surgical focus, and the only thing they have left is their arthritis, which is just as bad as ever and going on quite as merrily. I do not mean to infer that these cases should be treated without removal of surgical foci. There may yet be discovered a specific bacterium. Many investigators have found specific bacteria. Dr. Cecil is seemingly nearer than any one else and all hope that he has identified the specific bacterium of this disease; but if he has, something more than merely treatment by specific attack must be done for these patients as they are tired out, they are fatigued, they are weary; they have other disturbances than those which their bacterial foci may have induced and which cannot be treated solely by bactericidal methods. I call attention to the third paragraph of this concept of the committee, of which Dr. Pemberton, Dr. Cecil and I happen to be members. We have all agreed to sign this: "It is the opinion of the committee that at the present time no single infectious agent or any completely defined dietary deficiency or metabolic disturbance has been conclusively shown to be the sole cause of these disorders. The committee inclines to the belief that any one of these factors or certain combinations of these factors under appropriate circumstances may basically underlie the onset of the disease." I happened to pick up this intriguing book of Haldane's and in it I found a paragraph that appeals to me strongly. He is talking about chronic diseases and says: "We are not likely to deal with them effectively on Pasteur's lines. We must divert our view from the microorganism to the patient. Where the doctor cannot deal with the former he can often keep the patient alive long enough to be able to do so himself."

STREPTOCOCCAL INFECTIONS OF THE EPIPHYSES AND SHORT BONES

THEIR RELATION TO KOHLER'S DISEASE OF THE TARSAL NAVICULAR, LEGG-PERTHES' DISEASE AND KIENBOCK'S DISEASE OF THE OS LUNATUM [*]

D. B. PHEMISTER, M.D.
ALEXANDER BRUNSCHWIG, M.D.
AND
LOIS DAY
CHICAGO

Bacteriologic studies have been undertaken in a group of obscure but kindred necrosing bone lesions, among which are Kohler's disease of the tarsal navicular, Legg-Perthes' disease, and Kienbock's disease of the carpal semilunar, in an endeavor to throw some light on their etiology. The most feasible causes to which they have been attributed may be grouped under the headings of infection, embolism and trauma. Axhausen considers the condition an anemic infarction from a mycotic embolus or a thrombus but without bacterial infection of the field. While these and the kindred necrosing lesions have been studied pathologically in great detail, particularly by the Germans, they have been investigated very little from a bacteriologic standpoint. In the few cases in which cultures have been made, they have usually been reported as sterile. In this series, cultures have been taken in two cases, each of Kohler's disease of the tarsal navicular bones, Legg-Perthes' disease, and Kienbock's disease of the lunatum. Streptococci grew in the cultures of four cases: one of Kohler's disease, one of Legg-Perthes' disease, and two of Kienbock's malacia. In one case of Kohler's disease in a child with multiple osseous and glandular tuberculosis, the cultures were sterile and guinea-pig inoculations were negative for tuberculosis.

[*] Read before the Section on Orthopedic Surgery at the Eighty-First Annual Session of the American Medical Association, Detroit, June 27, 1930.

Case 1.—*Kohler's disease.* A boy, aged 7, who entered the University of Chicago Clinics, Dec. 10, 1929, began to have pain in the medial midtarsal region of the left foot, thirty hours before admission. It soon became severe enough to prevent him from walking, and he developed malaise and fever. Six weeks previously he had an attack of sore throat with fever, enlargement of the upper cervical lymph nodes, discharge from the left ear, and an erythematous skin eruption which lasted three or four days. The fever and malaise lasted several days and he was in bed for about two weeks. The ear continued to discharge until recently and the general run-down condition has persisted to date.

Physical examination revealed a poorly nourished boy who appeared to be acutely ill and who experienced severe pain on movement of the left foot. The temperature at admission was 101 F. Regional examination showed the tonsils enlarged, cryptic and slightly inflamed. The upper deep cervical lymph nodes were slightly enlarged. There was no discharge from the ears. The heart was of normal size and no abnormal sounds were heard over it. The extremities were normal aside from the left foot, which was slightly swollen and markedly tender in the region of the left navicular bone. Blood examination revealed: red blood cells, 4,800,000; hemoglobin, 80 per cent; white blood cells, 19,000. Differential count: polymorphonuclears, 75 per cent; large lymphocytes, 3 per cent; small lymphocytes, 18 per cent; mononuclears, 4 per cent. Blood cultures were made on three flasks of dextrose broth and four tubes of Rosenow's brain broth. A roentgenogram (fig. 1) showed the shadow of the bony center in the left tarsal navicular to be irregular in outline and narrowed in its longitudinal axis. There was irregular reduction in density in its dorsal and distal portion, with increased density in its central portion. Roentgenograms of the right foot showed a normal shadow of the navicular bone.

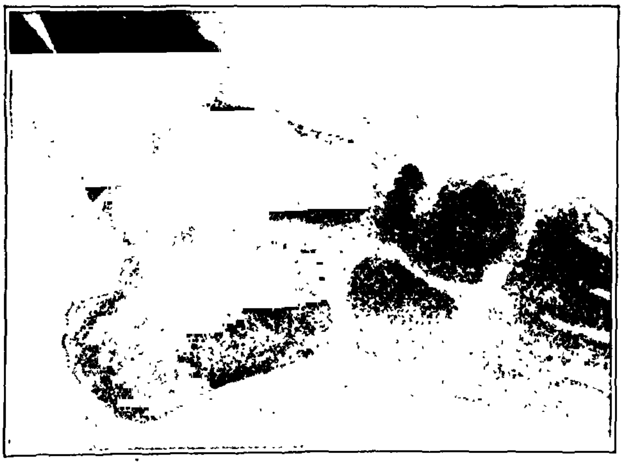

Fig. 1 (case 1).—Latent lesion of os naviculare producing symptoms for thirty hours.

At operation, thirty-six hours after onset of symptoms, the navicular bone was exposed through a dorsomedial incision. There was slight edema of the tissues about it and a slightly turbid fluid in the talonavicular joint. The navicular bone was excised and the wound closed without drainage.

The patient continued moderately septic for three days, after which the temperature gradually subsided and remained practically normal after the ninth day. Because of the fever, the wound was opened after twenty-four hours, but there was only a slight serohemorrhagic discharge from it for a short time afterward. The patient's general condition gradually improved and he was discharged with a healed wound four weeks after admission, since which time he has remained well. Tonsillectomy was done two months later.

The navicular bone, which was broken in two during removal, showed little change from the outside aside from the flattening. The cartilaginous periphery was from 2 to 3 mm. thick and not perforated. The center of ossification was irregular and broken down in part of its extent and replaced by brownish gray soft tissue. No pus was seen, but the bony area looked congested.

Microscopic examination of sections of a fragment of the navicular bone revealed evidences of both old and very recent changes. There was extensive destruction of bone and marginal destruction of cartilage along the osteocartilaginous junction at one side with filling out of the area by young connective tissue, which was necrotic in places and which surrounded and was absorbing small particles of dead bone in other places (fig. 2). In some places there was active formation of new cartilage and bony trabeculae along the inner surface of the cartilage (fig. 3). On the side opposite the area of destruction there was some old bone with extensive new bone formation in and about it which gave a greater density than normal. The cartilage was irregularly fissured and necrotic about the walls of the fissures, which in some places had been invaded by granulation tissue and in others by extravasated blood. This part of the picture was that of a destructive lesion of the bone of at least a few weeks' standing, which had resulted in necrosis and absorption of a large part of the center of ossification and of a small amount of cartilage with extensive absorption of the dead bone by fibroblastic tissue and partial repair by the formation of new bone and cartilage. In addition to this older change there was an acute inflammation through the bony center. The cancellous spaces of the new bone were extensively infiltrated with leukocytes and the blood vessels were engorged with red cells and a few leukocytes (fig. 4). There was also a moderate leukocytic infiltration of the living and necrotic fibroblastic tissue in the regions where bone had been destroyed.

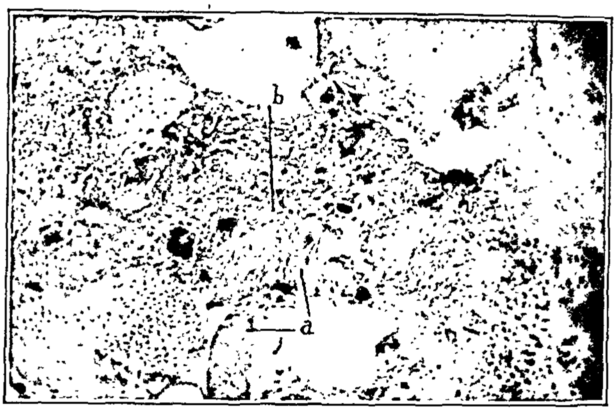

Fig. 2 (case 1).—Junction of cartilage and bone showing necrosis and absorption of bone (*a*) by young connective tissue containing some leukocytes, and (*b*) formation of new bone and cartilage; reduced from a photomicrograph with a magnification of 100 diameters.

Cultures were made of the bone as follows: Small chips were dropped into three tubes of Rosenow's medium (sheep's brain broth with marble) and two tubes of ascites dextrose broth. Ground material was placed in three tubes of Rosenow's medium and five tubes of ascites broth. Ground material was also implanted on five blood agar plates, two of which were left open and three covered by paraffin. The broth cultures all contained a growth of a long chain streptococcus at the end of eighteen hours except three tubes of ascites broth, which remained sterile. There was a growth of streptococcus which was more hemolytic than green-producing on all of the aerobic and anaerobic blood agar plates. Subcultures were grown from all of the positive cultures. The organism produced a small zone of complete hemolysis when grown on thin plates of blood agar, but it produced a green zone with very little hemolysis on dextrose blood agar. The blood cultures all yielded the same organism as was obtained from the bone. Blood cultures taken twenty-four hours after operation remained sterile.

When the organism was grown in Dunham's peptone broth containing 1 per cent of lactose, maltose, mannite, saccharose, salicin or inulin there was no fermentation, but the addition of 10 per cent dextrose produced fermentation. The p_H, which was 7-6 at the start was reduced to 6-6 after five days of incubation.

Intracutaneous injections made twenty-four days postoperatively showed a strong reaction from 0.1 cc. of broth culture of the organism obtained from bone. *Staphylococcus aureus* produced a moderate reaction and stock *Streptococcus viridans* and Rosenow's medium produced only a faint reaction. A control skin test with the organism on another person gave a negative result.

Agglutination tests were attempted with the patient's serum, but spontaneous agglutination was so marked that the tests were unsatisfactory.

Early broth cultures killed dogs and rabbits in forty-eight hours but were nonpathogenic for guinea-pigs and mice. Later broth cultures injected into the femoral artery with talc emboli produced suppurative osteomyelitis, but no lesions in the short bones of the foot.

In this case there had been a latent lesion of the navicular bone bringing about the changes of Kohler's disease of at least a few weeks' standing. Accompanying this was an acute inflammatory change of recent date which no doubt began shortly before the onset of symptoms. The hemolyzing green-producing streptococcus that grew in the cultures undoubtedly came from the lesion and was not a contamination, as control cultures made of the surgeon's gloves, the skin and adjacent muscle remained sterile. The question is, then, whether the streptococcus was the cause of both the old and the recent lesions or whether it was a secondary invader and produced only the recent pyogenic inflammation superimposed on the picture of Kohler's disease. The evidence favors the view that the organism was there from the beginning and that a change either in virulence or in resistance was responsible for the acute condition which precipitated the symptoms shortly before operation. The original involvement probably went back to the time of the general disturbances accompanying the throat infection six weeks previously. It is impossible to say from pathologic observations whether it was an infarct due to a thrombus or embolus produced by the organism with subsequent activation and invasion of the infarcted field or whether it was a mild silent infection throughout the osseous center of the bone from the beginning. Mild localized osteomyelitis produced by a number of pyogenic organisms, including staphylococci, may remain symptomless for weeks or even months after the onset, as shown by the observations of Phemister [1] and others. The original throat infection with its complications was the type that is most frequently due to the streptococcus.

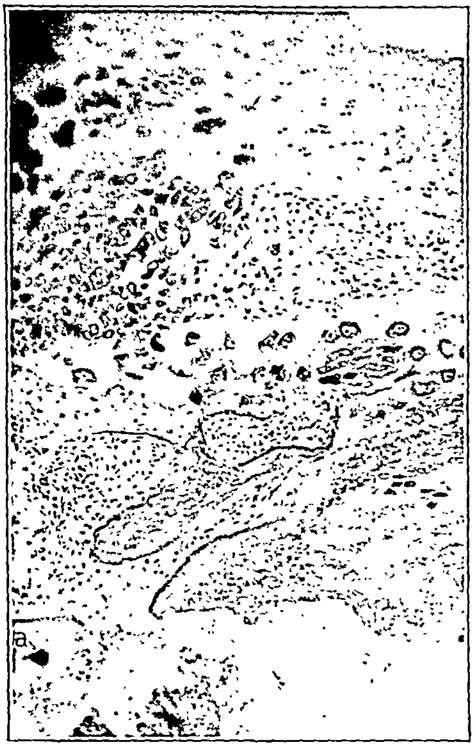

Fig. 3 (case 1).—Formation of new bone and cartilage and absorption of old necrotic bone (*a*); reduced from a photomicrograph with a magnification of 150 diameters.

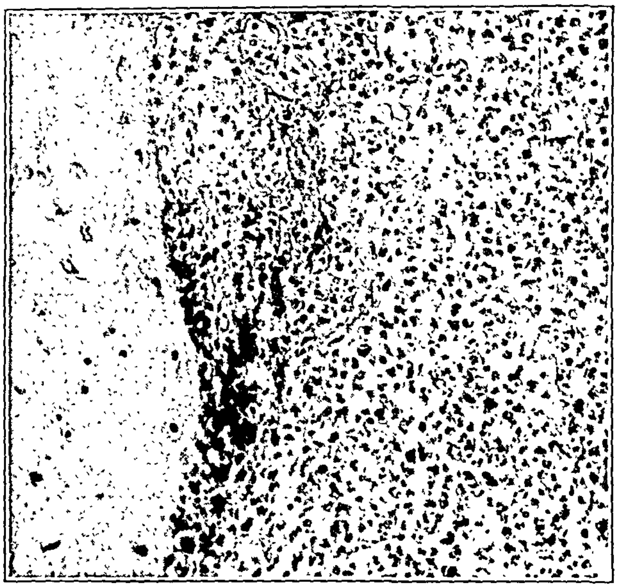

Fig. 4 (case 1).—Bone marrow showing infiltration with polymorphonuclear leukocytes; reduced from a photomicrograph with a magnification of 375 diameters.

Lecéne and Mouchet,[2] and Estor [3] have observed cases of Kohler's disease that clinically presented the picture of pyogenic infection, and Lecéne and Mouchet found pathologic evidences of inflammation in material removed at operation. However, we can find no reports of cultures of tissues made in any of the cases that have come to operation.

In the following case, a symptomless Kohler's disease was discovered accidentally in roentgenographing the bones for tuberculosis of the tibia:

Case 2.—A girl, aged 3, presented the clinical manifestations of tuberculosis of the upper cervical lymph nodes and extensive tuberculosis of the shafts of both ulnas, both humeri, the middle of the right tibia, and one metacarpal bone, all of which had developed within the previous two months. Roentgenologic examination confirmed the finding of tuberculosis of the bones. A roentgenogram of the right tibia incidentally disclosed the typical picture of Kohler's disease of the right tarsal navicular which had produced no symptoms (fig. 5).

[2] Lecéne R., and Mouchet, A.: Revue d'orthop. 11:105

[3] Estor, E.: Revue d'orthop. 12:365, 1924.

Subsequent examination revealed slight tenderness in the region of the bone. Biopsies were performed on an involved cervical lymph node and the foci in the right tibia and right tarsal navicular. Histologic examination of tissues from the lymph node and tibia revealed the typical picture of tuberculosis. The material obtained from the center of ossification in the navicular was broken down and microscopic examination showed necrotic bone, immature connective tissue and phagocytic tissue which in places was absorbing bone and cartilage while in others it was necrotic and hemorrhagic. No signs of tuberculosis were found histologically. Guinea-pig inoculations of the material from the navicular were negative for tuberculosis, and broth and aerobic and anaerobic blood agar cultures remained sterile. The child died at home six weeks later, presumably of the tuberculosis.

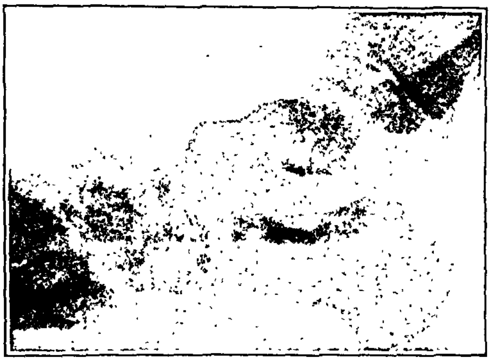

Fig. 5 (case 2).—Kohler's disease in child with multiple tuberculosis of bones and cervical lymph nodes.

In addition to emphasizing the fact that the lesion may develop silently, this case also suggests that tuberculosis may be one of the factors that brings about this group of diseases and supports Axhausen's[4] original assumption that they may be the result of a caseous tuberculous embolus which blocks the artery to the bone. Tuberculosis has been associated with it in other cases, as in the one reported by Massabuau and Marchand,[5] in which a nodule in contact with and apparently arising from a diseased navicular was excised and proved to be tuberculous by guinea-pig inoculation and histologic examination. In another of their cases, a fistula leading to the navicular developed that was assumed to be tuberculous.

LEGG-PERTHES' DISEASE

Evidence supporting the hypothesis that one of the causes of Legg-Perthes' disease may be pyogenic microorganisms is partly clinical and partly pathologic. There have been only a few reports of bacteriologic studies. *Staphylococcus aureus* grew in the cultures of patients operated on by Legg[6] and Kidner.[7] Aerobic cultures of a patient operated on by Phemister[8] remained sterile. The clinical evidence in certain cases is suggestive. The onset may be accompanied by fever, as in the case of McWhorter,[9] and the disease has developed in the course of or following an acute febrile polyarthritis, as reported by Perthes,[10] Brandes[11] and Sundt.[12] Histologic examination of lesions in the active stages shows necrosis of the bone and a marked fibroblastic and fixed tissue phagocytic reaction, absorption of the necrotic bone and necrosis of the fibroblastic tissue with usually little or no leukocytic infiltration, but sometimes with extensive extravasation of blood. In later stages there is more or less extensive regeneration of new bone and cartilage. Fairly large sequestrums have also been observed in the epiphysis which suggest infection.

Cultures were made of materials removed at operation in two cases:

Case 3.—A boy, aged 12, had slight pain and limp in both hips for a period of about one year which had developed without any apparent cause. Examination was essentially negative aside from enlarged tonsils and markedly restricted motion in both hips. A roentgenogram showed the picture of advanced Legg-Perthes' disease in both hips with flattened heads and broadened necks and a large oval area of reduced density in the juxta-epiphyseal portion of the superior and lateral portion of the left neck (fig. 6). Biopsy of the neck lesion was performed. There were several cubic centimeters of clear fluid in the hip joint. When the neck was opened, a cavity was found filled with dark fleshy tissue dotted with yellowish white necrotic specks and a few fine bony trabeculae. It was curetted. Dr. John Gordon made cultures of the material removed from the neck, on aerobic and anaerobic blood agar plates and deep shake blood agar tubes. An organism, which proved to be an alpha hemolyzing green-producing streptococcus, grew on the cultures. The wound healed by first intention but the condition of the patient was slightly febrile for two weeks and on the tenth day, when the temperature reached 100 F., a blood culture yielded the same organism as grew in cultures from the hip. Intravenous injections of the organisms in young dogs and rabbits failed to produce bone lesions.

Histologic examination of the tissues revealed extensive bone absorption with replacement by hemorrhagic and partly degenerated fibroblastic tissue. A small portion of cartilage of the head which was excised showed extensive erosion by the same type of tissue. There were areas of polymorphonuclear infiltration (fig. 7) and a good deal of extravasated blood. Small particles of bone sand were seen in the process of absorption.

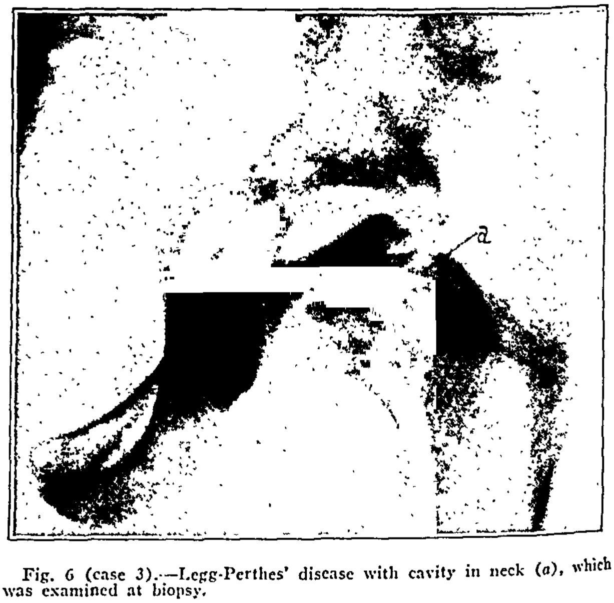

Fig. 6 (case 3).—Legg-Perthes' disease with cavity in neck (*a*), which was examined at biopsy.

The histologic picture was that of bone necrosis, fibroblastic proliferation and necrosis, hemorrhage and leukocytic infiltration. The patient gradually recovered from the symptoms, and five years later presented healed but extensively deformed heads of the femurs with moderate limitation of motion about equal in the two joints. It appears reasonable to assume that the organism grown in the cultures from the neck of the femur were contained in the tissue removed, and this is substantiated by the growth of the same organism in a blood culture made eight days postoperatively. There still remains the question as

to whether the organisms were the cause of the disease or were secondary invaders from the blood stream.

Case 4.—A girl, aged 7, had pain in the right hip for one month beginning four and one-half months before examination. A limp developed soon after the onset of pain and has continued since. There had been no sore throat or pyrexia since the onset of the trouble. Examination gave essentially negative results except that the right hip showed marked limitation of abduction and rotation and moderate limitation of flexion. A roentgenogram showed flattening of the head and broadening of the neck of the right femur, with increased density of the lateral portion of the head (fig. 8). A biopsy was performed.

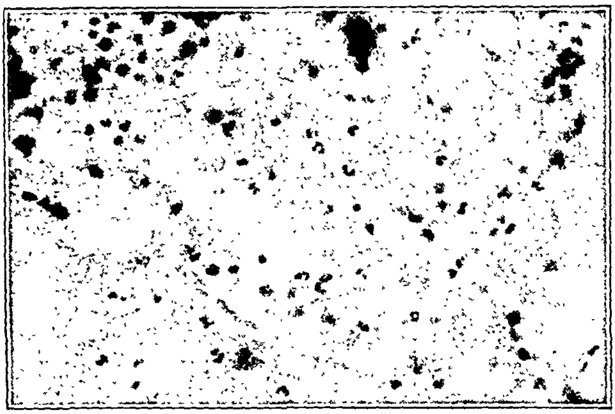

Fig. 7 (case 3).—Leukocytic infiltration of the breaking down tissues occupying cavity in neck.

On exposure of the hip there was no excess of joint fluid and no change in the synovia. The head was flat and smooth. A window of cartilage was excised from it, exposing a cavity containing dark to gray soft tissue in which were small particles of bone. Most of the center was curetted out.

Five tubes of Rosenow's sheep's brain broth and three tubes of ascites broth were inoculated with unground particles of curettings. Four Rosenow's and two ascites broth tubes were inoculated with ground tissue; four blood agar plates were smeared with ground tissue, two of which were then sealed with paraffin. There was no growth in any of the cultures after twenty-one days of incubation.

Histologically, some of the bone was broken down and the space occupied by fibroblastic tissue in which were embedded small particles of necrotic bone that were being absorbed. A few giant cells were present, but there were practically no leukocytes and there was very little cartilage or bone proliferation (fig. 9). Postoperatively, the curetted region rapidly filled with dense new bone while the small mesial portion of the head that was not curetted remained porous. Figure 11 shows the appearance seventy-six days after operation. The function of the hip was then about the same as before operation.

That one cause of necrosis of the growing femoral head may be traumatism is supported by the facts that it sometimes follows closed reduction of congenital dislocation of the hip and that in Nussbaum's experiments of cutting the epiphyseal vessels necrosis and subsequent deformity resulted.

Mau[13] has shown experimentally that continuous compression of the partially ossified vertebra of the artificially kyphosed tail of a young rat will injure the vessels running through the cartilage to the center of ossification on the concave side and result in necrosis of the bone of the epiphyses with subsequent irregularity and deformity during the period of reconstruction.

No record could be found of bacteriologic examination of tissues removed in cases of Kienbock's disease of the carpal lunatum. However, Gold[14] reports a histologic examination of one case showing the usual picture of bone necrosis as well as extensive leukocytic infiltration with the formation of a small abscess. The persistent pain and the swelling at the onset in many cases suggest a low grade infection, but sections of the excised tissue usually show extensive necrotic, absorptive, and reparative changes with no infiltrative cells. Cultures were made of the tissue removed in the following two cases:

Case 5.—A man, aged 20, had pain and stiffness in the right wrist of eight months' duration. While working as a pipe cutter he developed pain, swelling and tenderness in the right wrist. The swelling disappeared but pain and stiffness continued and were always worse after usage. Examination eight months after the onset showed limitation of motion in the wrist and tenderness over the lunatum. A roentgenogram (fig. 10) revealed slight collapse of the proximal side of the lunatum with subcortical reduction in density and slight irregular increase in density of the central and ulnar portions of the bone. A lateral view revealed flattening of the lunatum most marked dorsally. An operation was performed, which consisted of excision of the lunatum in two fragments through a dorsal incision. The wound was closed and it healed by primary union. The larger dorsal fragment was flattened and contained a small cavity filled with dark gray fleshy material. The palmar fragment consisted of dense bone. Cultures were made of small chips in eight tubes of Rosenow's sheep's brain broth and one tube of ascites broth. Fragments were ground in a closed mortar and cultures were made on two tubes of Rosenow's medium and two of ascites broth. Four blood agar plates were smeared with ground material, two of which were then coated with paraffin. There was a growth of long chain streptococcus in forty-eight hours on two Rosenow tubes, and in the ascites broth inoculated with unground material. There was a similar growth in all the cultures on blood agar plates inoculated with the ground material in from twenty-four to forty-eight hours. It was a green-producing alpha hemolyzing bile insoluble organism growing scantily in short chains. Agglutination tests with the patient's serum were unsatisfactory because of spontaneous clumping. Fermentation tests showed slight acid production after five days of growth in Dunham's peptone broth containing 1 per cent lactose, maltose, mannite, saccharose, salicin or inulin. Skin tests thirteen days postoperatively with a 0.1 cc. intradermal wheal gave, in twenty-four hours, a marked reaction with the dead bacteria obtained in cultures from the tissue, a more marked reaction from

14. Gold, cited by Axhausen, Arch. f. klin. Chir. 151: 72, 1928.

staphylococci, a slight reaction from another strain of *Streptococcus viridans,* and no reaction from Rosenow's medium.

The femoral artery in three dogs was injected with 2 cc. of a suspension of talc and bacterial sediment. One dog died in twelve days and another in twenty-two days from severe osteomyelitis of the leg and foot bones and gangrene of the soft parts. The third dog developed acute osteomyelitis of the leg and foot bones, which had passed into the chronic sclerosing stage, and streptococci were not recovered from the tibia in cultures made at necropsy eight and one-third months later.

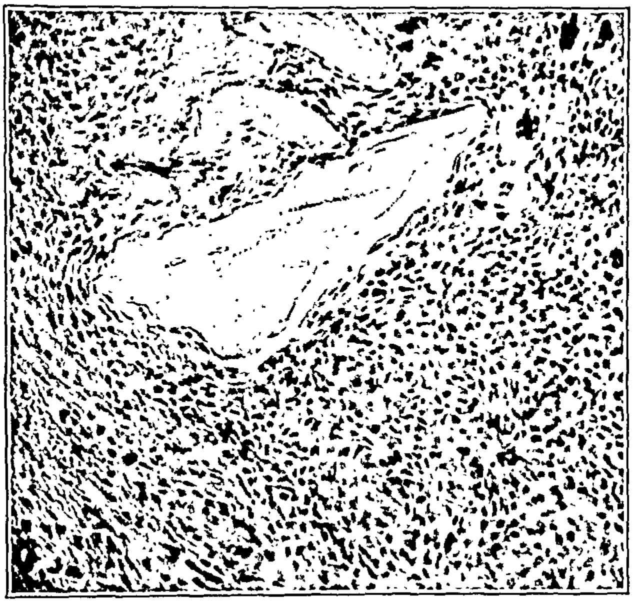

Fig. 9 (case 4).—Necrotic bone and fibroblastic and fixed tissue phagocytic reaction.

Microscopic sections of the lunatum showed central necrosis and breaking down of bone by fibroblastic tissue with considerable absorption of cartilage. There was practically no leukocytic infiltration. In some regions there was extensive regeneration of bone and cartilage. The process of transformation was one of absorption and replacement of the dead bone by fibroblastic tissue, which in turn was being replaced by new bone formed from surviving old bone rather than one of creeping substitution of the dead bone by new as occurs extensively in the organization of areas of aseptic necrosis.

Case 6.—A man, aged 20, developed pain and limitation of motion in the right wrist eleven months before admission to the hospital. The symptoms gradually increased in severity. Roentgenograms taken ten and one-half months, nine months and three months before, and at the time of examination revealed early slight increase in density and deformity with a progressive reduction in density and collapse of the semilunar bone. An operation was done, consisting of an excision of the lunatum through a dorsal incision and closure of the wound, which was followed by primary healing. The dorsal two fifths showed an extensive cavity filled with necrotic débris. The palmar portion was irregular in outline but consisted of dense trabeculated bone. There was a thin irregular layer of cartilage about the periphery. Aerobic and anaerobic cultures were made on blood agar plates and two cultures on dextrose blood broth. The tubes of dextrose blood broth showed clouding in twenty-four hours; there was a growth of long chain streptococcus in each tube. Two rabbits were each injected intravenously with 5 cc. of the broth culture. The original cultures were killed over night by a defective incubator. The rabbits showed no change and were killed at the end of forty-eight hours. A femur was removed from each animal for culture. Those from the bone marrow of one remained sterile, while in the others a green-producing alpha hemolyzing streptococcus was grown. Whether the organism growing in the cultures from the rabbit was the same as that growing in the cultures of the lunatum is very questionable.

COMMENT

The organisms grown in the cultures of these four cases were either the cause of the disease or secondary invaders or contaminants. The significance of the bacteriologic observations varies with each case. In case 1 there can be no doubt about the presence of a hemolyzing streptococcus which on certain mediums showed a decided tendency to the production of a green zone and which had produced the picture of infection in the bone. It seems logical to assume that it lodged in the bone early in the course of the throat infection, producing mild symptomless inflammation with necrosis, which was followed by an absorptive and regenerative period. Then there came an acute exacerbation of the infection with the onset of symptoms and the formation of the picture of acute osteomyelitis. It would be far-fetched to assume that the older picture of Kohler's disease was produced by a noninfectious agent and that the acute pyogenic reaction was due to a recent secondary invasion by the streptococcus. There is more room to doubt that the streptococci isolated in cases 3, 4 and 6 were the cause of the disease, as there was no acute inflammatory reaction manifested either clinically or pathologically at the time of operation and of culture of the tissues, except for a rather extensive polymorphonuclear infiltration in case 4. Secondary invasion of relatively benign bone lesions by streptococci has not been proved for other diseases. The assumption is favored somewhat by the fact that the bone marrow is a filter for and may possibly harbor for a time bacteria entering the body by way of the blood stream.

CONTROL CULTURES

The view that the organisms in these cases were obtained from cultures made from the diseased tissues is greatly strengthened by a series of controls in which apparently noninfected tissues were removed in the same operating room and cultures made from them in the same laboratory under identical conditions. Cultures were made from thirty-nine tissues in Rosenow's sheep's brain broth with marble, which affords opportunity for growth of bacteria at all degrees of oxygen tension. Of these, 14 were bone and bone marrow, 5 cartilage, 9 muscle, 6 fat and fascia, 3 synovia, 1 nerve, and 1 thyroid gland. Of 85 tubes inoculated there were growths on 13, of which 9 were staphylococcus, 2 *Bacillus subtilis,* 1 diphtheroid, and only 1 *Streptococcus viridans.* The *Streptococcus viridans* grew in cultures of the synovial lining of a hip joint in a case in which a Whitman reconstruction operation was done for ununited fracture of the neck of the femur of two months' standing. There are numerous reports of control cultures of clean wounds showing staphylococci as a contamination arising apparently from the skin, in as high a percentage of cases as it was found here.

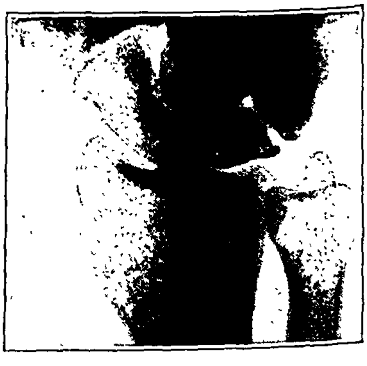

Fig. 10 (case 5).—Kienbock's disease of lunatum of eight months' standing.

The impression has been gained that streptococci are rarely contaminants of cultures made of wounds at operation. Cecil[15] reports the finding of a slightly hemolysing green-producing streptococcus in 4 per cent of blood cultures made on persons free from clinical signs of infection. The fact that the wounds in these cases healed by primary intention is no argument against the presence of streptococci, as surgical experience has shown that when they are present in low virulence they do not produce evident infection of the operative wound. This is the case after operations on chronic arthritic joints from which *Streptococcus viridans* has been grown. Streptococci are among the commonest causes of vegetations in the left side of the heart which lead to arterial embolism. Thus, *Streptococcus viridans* is the cause of subacute bacterial endocarditis which frequently leads to embolism and infarction of the viscera containing end-arteries as the spleen and kidneys, which lesions, although they are infected by the organism, do not suppurate.

Rheumatic endocarditis involving the left side of the heart may also produce embolism and infarction. While the bacteriology of rheumatic fever is still unsettled, the organism that has most frequently been isolated in the disease has been a streptococcus belonging to one of the two broad groups of *Streptococcus viridans* and anhemolytic streptococci. The recent work of Von Glahn and Pappenheimer[16] has shown that in rheumatic fever and rheumatic heart disease there is more or less extensive involvement of the blood vessels producing localized arteritis in smaller vessels. Such lesions might lead to blockage of the arteries from thickening of the wall, from thrombosis or from embolism.

There appears to have been no extensive search made for infarcts either sterile or infected with these organisms in the bones in the diseases enumerated and there have been no cases of necrosing lesions of the epiphyses and short bones associated with endocarditis or multiple arthritis of any form except those previously mentioned in connection with Legg-Perthes' disease.

In view of what is known about the pathogenicity of the less virulent form of streptococci and in view of the positive bacteriologic observations in these four cases it is not improbable that in each case the organisms were the cause either direct or indirect of the disease. If they were the direct cause, it was by lodgment of the bacteria in the bone, as in ordinary pyogenic osteomyelitis with the production of a quiet type of inflammation characterized by extensive necrosis and a fibroblastic and fixed tissue phagocytic rather than an infiltrative cellular reaction. If they were the indirect cause, they first produced either a thrombus or vegetation in the heart or arteries, which reached the bone as an embolus, or they produced a local obliterating arteritis or thrombosis within the bone itself, cutting off the blood supply and creating a bone infarct. If this was the case, then the infarcted area was invaded by the bacteria so that it would be improper to speak of the lesion, as Axhausen does, as "aseptic infarction," since it is septic infarction, the infection being of low grade. That aseptic infarction might be possible, owing to the low virulence of or the acquired immunity against the organism which produced the embolus, is shown by case 5, in which the cultures were sterile, although earlier cultures might have shown the organism.

The pathologic changes in these cases are different from those following aseptic bone necrosis due to severance of blood vessels as in bone transplants, and the femoral head in certain cases of intracapsular fracture of the neck of the femur followed by bony union of the fracture. In these reported cases with positive cultures and in case 4, the bone was largely absorbed and replaced by fibroblastic tissue and fixed tissue phagocytes which either persisted or underwent necrosis or were replaced by dense new bone formed from areas of old bone which had survived. On the other hand, in aseptic necrosis from vascular severance the dead bone is invaded by blood vessels and osteoblasts and there is simultaneous absorption and partial replacement of dead bone by new bone, a process known as creeping substitution.

It is a curious fact that while primary staphylococcus infections of the shafts are common they are very rare in the epiphysis and short bones involved in this group of diseases.

SUMMARY

1. Bacteriologic studies were made of biopsy material of two cases each of Kohler's disease of the tarsal scaphoid, Legg-Perthes' disease and Kienbock's malacia of the os lunatum. Streptococci grew in cultures of four cases and cultures of two remained sterile.
2. A streptococcus which on blood agar plates was more hemolysing than green-producing and on dextrose blood agar plates was more green-producing than hemolysing grew on cultures of one case of Kohler's disease showing acute symptoms.
3. Green-producing streptococci grew on cultures of one case of Legg-Perthes' disease and one case of Kienbock's malacia.
4. A streptococcus which was not further identified grew in cultures of one case of Kienbock's malacia.
5. One case of Kohler's disease, cultures and guinea-pig inoculations of which were negative, occurred in association with multiple osseous and lymph glandular tuberculosis.
6. One case of apparent Kohler's disease developed following traumatism.
7. These observations suggest that streptococci play an important rôle in the etiology of these diseases but that other factors may also bring them about. Whether the streptococci reach the bone in an embolus which blocks the main artery or whether they lodge there alone remains undetermined.

ABSTRACT OF DISCUSSION

Dr. Oscar L. Miller, Charlotte, N. C.: The inquiry which Dr. Phemister keeps up on this and other allied subjects is most interesting. I have always had an open mind in regard to infectious or traumatic origin of the diseases he is discussing. Certainly some cases of Legg-Perthes' disease show disturbance of bone texture similar to what physicians are taught to believe is destruction by infection. It may yet be proved that the so-called aseptic necroses may have had an infectious origin. The infectious phase may be short but may destroy the blood supply to portions of the bone and then the aseptic phase ensues.

Dr. J. Albert Key, St. Louis: At present every one looks a little askance at results in which *Streptococcus viridans* is incriminated. At the same time it is known that that organism, among others, is capable of creating a low grade lesion in bone which may later subside and become sterile. Consequently, sterile cultures from these lesions do not mean that they were not originally bacterial, nor do sterile cultures mean that bacteria are not present, because the right culture medium may not be available for the particular organism. There is another possibility. Dr. I. A. Kendall tells me that he is able to attenuate organisms to a point at which they will be alive and produce toxin but have lost the power of reproduction. Several years ago Dr. Phemister reported recovering *Streptococcus viridans* from bone cysts. I have taken cultures in three cases and have grown low grade staphylococci in all. Two may have been contaminations. One I am sure was not a contamination, because I took smears at the operating table and in one instance I got over a hundred colonies on one blood agar plate. This is interesting in view of the recent work in which all the bone cysts are being laid to hyperactivity of the parathyroids. In the cases which Dr. Phemister presented the fact must be considered that two of them look like metastatic abscesses; that is, the patient had casual streptococci in the blood stream which landed on the head of the femur or scaphoid and caused disease. If the etiology of these conditions is going to be settled, a lot of people must work on them to decide whether or not they are infectious, rather uniform results must be obtained, and these must come from people whose work can be credited and controlled. Osgood-Schlatter's disease of the tibial tubercle is rather common. It is quite acute at times and can be opened up and a wedge shaped piece removed and the patient can get up as soon as the wound is healed. In my experience, limited to one operative case, that greatly shortens the period of disability. In a bilateral case, I removed wedges and the boy had no further symptoms. The specimens showed low grade granulation tissue and small cysts in the cartilage. I took ten cultures from each tibial tubercle. Diphtheroid organisms grew in two of the cultures. I put these into the tibial tubercles in young rabbits and dogs, but they did not develop Osgood-Schlatter's disease.

[16] Von Glahn, W. C., and Pappenheimer, A. M.: Tr A. Am. Physicians, 1928, p. 203.

Dr. C. B. Francisco, Kansas City, Mo.: I should like to say following up Dr. Key's remarks about the tibial tubercle that that offers the best group of cases for study. I have begun to study the tissue of the anterior tubercle from the cultural standpoint and hope to be able to get some information, although I doubt whether infection is the cause of any of these conditions. In regard to Dr. Phemister's case of the bilateral Koehler's disease, the first case that he showed, one always wonders, in taking a history of such a case, whether the child did not have this condition before it had the illness. That may have been responsible for these germs getting down to this location where the resistance was lower; so that one is still conning over as to whether the infection is the cause of the condition, when the infection is found, or whether the infection locates there as a result of the tissue's resistance being lowered.

Dr. D. B. Phemister, Chicago: Dr. Key referred to the fact that the micro-organisms in these conditions might be secondary invaders. This is quite true, but on the whole it is safer to explain disease processes on the basis of one factor rather than several. Osgood-Schlatter's disease belongs in this group. I have recently seen a case in which the disease was bilateral but on one side there were two areas of reduced density in the metaphysis of the upper end of the tibia that were suggestive of bone infarcts. Consequently the lesions in the tibial tubercle may have been due to the same underlying cause. *Streptococcus viridans* is an organism that makes low grade infectious processes involving the soft parts and it would be strange if the skeleton should be immune to it. The difficulty in deciding whether or not it is an etiologic factor lies in the fact that it may be a secondary invader of other lesions in the soft parts and the same may apply to bone.

USE OF IODIZED OIL IN DIAGNOSIS OF NASAL SINUS CONDITIONS

FURTHER OBSERVATIONS *

HENRY M. GOODYEAR, M.D.
CINCINNATI

Late in the year of 1925, prompted by the work of the French in the demonstration of iodized oils in the spinal column and in the ventricles of the brain, I made my first roentgenograms with 40 per cent iodized poppy-seed oil (lipiodol) injected into the antrums. A study of thirty-five cases of various sinuses injected (except ethmoids) were reported[1] with lantern slides in March, 1926, before the Cincinnati Academy of Medicine. In the same month Fraser[2] reported a similar series in southern Michigan.

During the following month Proetz[3] read a paper before this section at Dallas on displacement and the use of iodized oils and in May, 1926, MacCready[4] presented a paper on the use of iodized poppy-seed oil in the antrums. These constituted the first recorded papers read in this country devoted to the use of iodized oils in nasal sinuses.

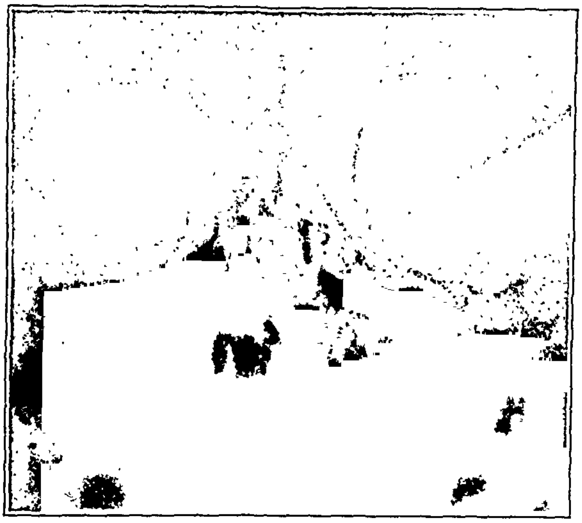

Fig. 1.—A patient, aged 43, had had bronchial cough for two years; no history of any nasal disturbance; transillumination, right; dark; 3 cc. of iodized poppy-seed oil 13 per cent retained. At operation a thick cystic membrane was completely removed; cough disappeared six weeks later.

The value of iodized poppy-seed oil in diagnosing nasal sinus conditions was quickly realized and today, in a matter of four years, its use is more or less familiar to every one in the practice of rhinology, thus marking the progress of a new and important step in sinus diagnosis.

It was thirty-three years ago (1897) that Scheir first diagnosed pus in the nasal sinus by radiography and confirmed the diagnosis by irrigation. Further work by such men as Pfahler, Coakley, Mosher and Caldwell established the fundamentals and it appeared that every antrum could be diagnosed by roentgenograms. These observations soon proved to be inaccurate. However, their work marked a new era in the diagnosis of sinus conditions, and now another step has been taken beyond the simple roentgenogram.

The use of stereoscopic views is also increasing and their importance, with or without opaque oils, is watched with interest.

Today in the search for the focus of infection in chronic bronchial coughs, unaccountable elevations of temperature, arthritis, chronic myocarditis, pyelitis, cystitis, various eye conditions, and headaches, it is not sufficient to report that the nose shows no evidence of polypi or pus. The roentgenogram may show slight changes or none and the antrum lavage may be negative. Yet these observations are neither final nor sufficient.

---

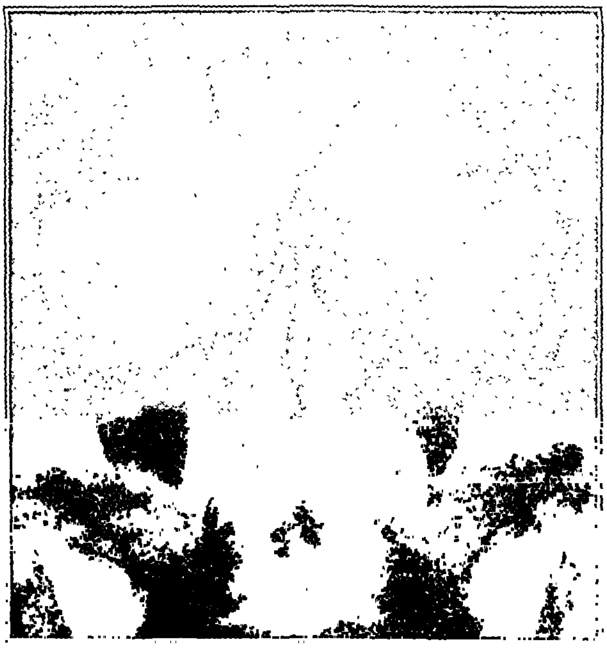

Fig. 2.—Marked filling defect on both sides in a patient who complained of intermittent arthritis and postnasal dripping. Plainly a case for radical operation.

Too many important cases show a haziness in roentgenograms and a negative lavage yet with opaque oils a definite filling defect is found which proves on operation to be a cystic membrane often dotted with small abscesses in its walls. It is these patients especially, suffering from some undetermined source of infection, that may be relieved by operation or saved from an unnecessary exploration of the sinuses (fig. 1). The type of operation may also be more accurately determined. If there is a generalized marked thickening of the membrane of the sinus involved, a radical operation would be chosen (fig. 2), whereas a filling defect confined to the floor of an antrum might yield readily to an intranasal window resection and curettement of the sinus floor.

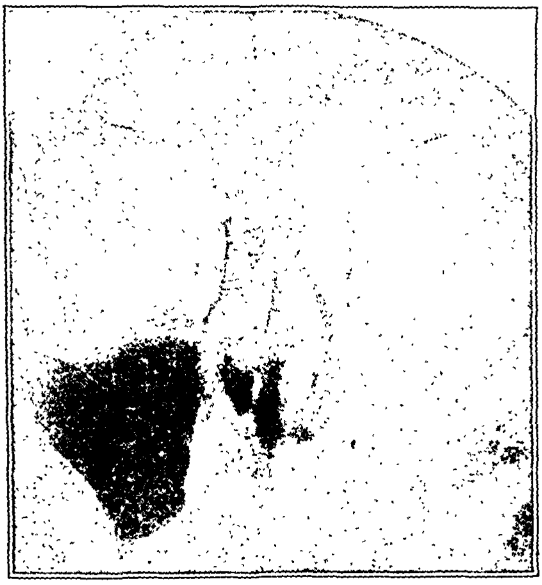

Fig. 3.—The roentgenogram was taken in the nose-chin position. The oil has extended from the antrum to the ethmoid area and a small amount shows in the frontal sinus. To be compared with figure 4.

My experience of almost routine use of opaque oils when roentgenograms have been indicated during the past four years has convinced me that the greatest practical value of opaque oils is in determining the condition of the antrums. And I believe that the future increasing use of the oils, except in very special cases, will be largely confined to the maxillary sinuses.

My reasons for the foregoing conclusions are these:

1. The antrum, because of its dependent position and relation to the teeth, is more frequently infected than any other sinus.

2. The filling of the antrum is easier to do and less difficult to read on the roentgenogram.

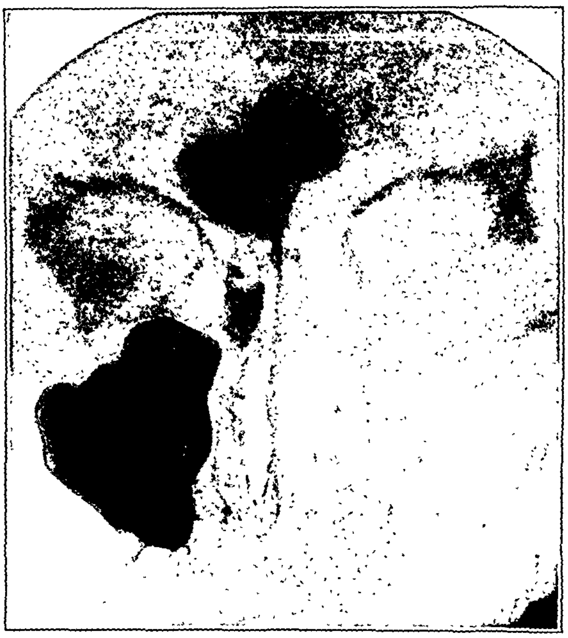

Fig. 4.—Same patient as in figure 3, approximately two minutes later in nose-forehead position. The rapid migration of oil to the frontal sinus between exposures should be noted. Pus must extend rapidly from the antrums to the ethmoids and frontals. This probably accounts for some of the frontal pain accompanying an acute infection of the antrum.

3. Contrary to the general teachings, ethmoid and frontal sinus infections are probably more commonly secondary to an infection of the antrum than the reverse; thus one is more often determining the primary source. Roentgenograms of the course of the oil leaving the antrum rather suggest this conclusion. With the head in the recumbent position it may be only a matter of one or two minutes from the time the oil leaves the antrum till it enters the ethmoid area and frontal sinus (figs. 3 and 4).

With these pictures in mind it is not difficult to imagine what must happen when a patient lies down at night with the antrum filled with pus. One may also thus account for some of the frontal pain that so frequently accompanies an acute antrum infection.

4. The frontal sinuses, because of their position and drainage, less frequently require surgical intervention

and more readily show pathologic changes on roentgen examination, with possibly the exception of mucoceles, than any other sinuses. Thus it is only in obscure cases in which surgical intervention is contemplated that opaque oils are indicated for further diagnosis.

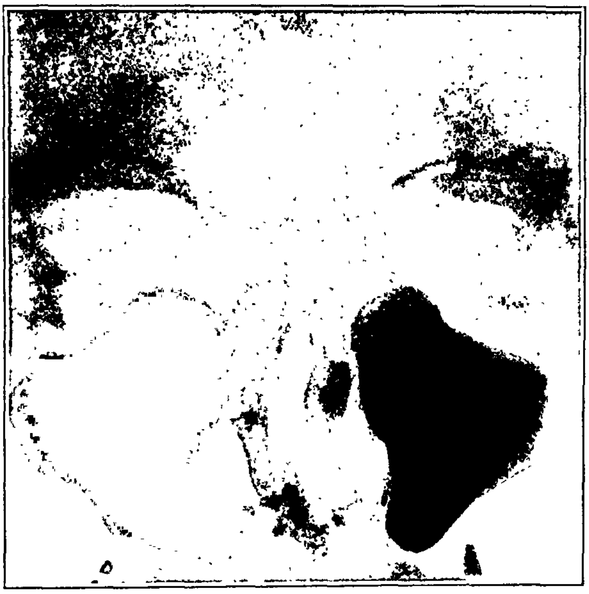

Fig. 5.—Iodized poppy-seed oil diluted 2 to 1 with heavy liquid petrolatum. The extremely heavy oil makes filling above the level of the ostium possible. Dry cotton is immediately packed in the middle meatuses and the patient sent two floors away for roentgen examination.

5. The sphenoids, which may be rather satisfactorily filled by the direct or displacement method, do not come up so often for diagnosis. Their condition can also be more nearly determined by the use of the nasopharyngoscope and by passing an applicator directly into the sinus, or even by enlarging the ostium for direct examination. Opaque oils here find their greatest value in determining the position and extent of the cavity.

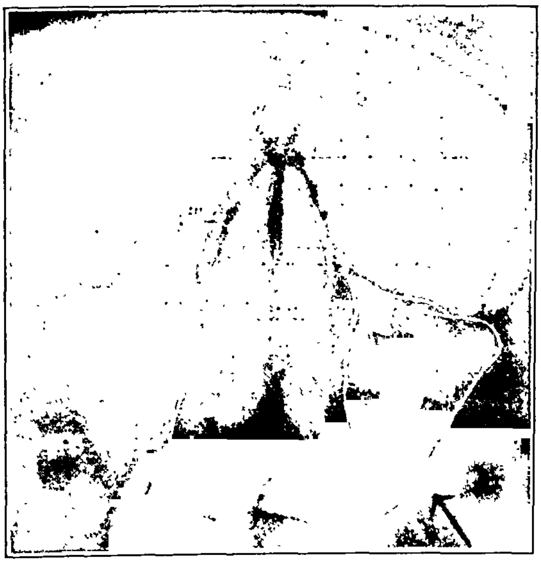

Fig. 6.—Prominent filling defect in a man, aged 48, one week after an acute coryza, with no pus on irrigation. Iodized oil was immediately injected. Two weeks later only the slightest thickening could be detected.

6. The ethmoids, which have been so beautifully demonstrated by Dr. Proetz with a displacement filling, offer a number of technical difficulties which have discouraged many workers. Too often, it is found that no oil enters the ethmoid cells at all or enters only one cell, yet these cells cannot be condemned on these observations. Moreover, as Dr. Proetz has stated, the exact angulation must be maintained at the seventy-two hour reading as was used for the primary roentgenograms, thus offering a source of considerable error.

TYPE OF OIL USED

1. Briefly, iodized poppy-seed oil, 40 per cent, diluted with two parts of heavy liquid petrolatum, has given most satisfactory results. In this dilution it will cast a shadow equal to or greater than that of full strength brominized sesame oil.

2. Brominized sesame oil, full strength, is less viscous and undoubtedly has its advantage in displacement and insufflation methods, and in patients sensitive to iodine.

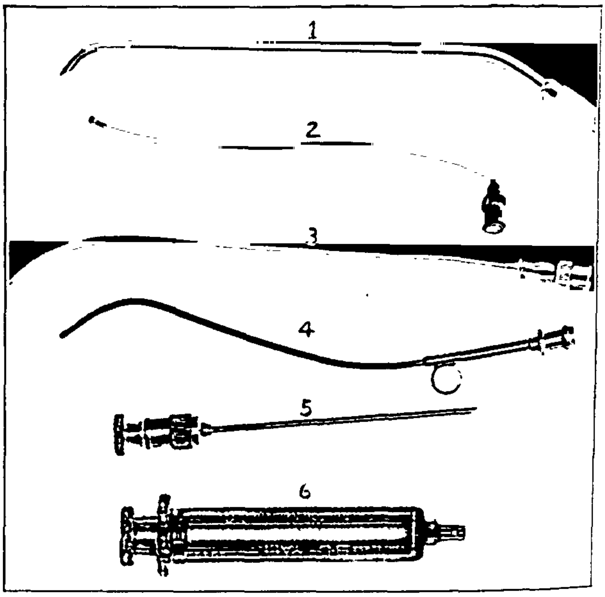

Fig. 7.—Instruments used with Luer fittings: (1) sharp cannula for anterior wall of the sphenoid sinus; (2) silver cannula for frontal with right angle Luer tip; (3) silver cannula for filling through mouth of sphenoid sinus; (4) steel cannula, 16 gage, for filling antrum through the middle meatus; (5) straight 17 gage needle for use in the inferior meatus, and (6) syringe.

3. Iodized rape-seed oil is a new American product which mixes readily with oil and casts an excellent shadow in a 50 per cent dilution.[5]

Iodism can practically be disregarded in the use of iodized oils in the foregoing dilutions. If the patient should be particularly sensitive to iodine the sinuses may be irrigated or suction used to remove the oil after roentgenography.

Iodized poppy-seed oil diluted with heavy liquid petrolatum offers a viscosity which is an advantage in antrum and sphenoid injections as it is slow in leaving the sinus, thus permitting fillings even above the normal ostium (fig. 5).

I do not practice irrigation prior to oil injections. However, it may be done as the water is displaced by the heavy oil, if done immediately after irrigation. If one waits twenty-four hours the lavage may produce some swelling of the sinus membrane, which would displace the oil. For this reason I try never to use iodized oil within a week or preferably ten days after an irrigation.

---

[5] It has not yet been found acceptable by the Council on Pharmacy and Chemistry.

Acute nasal infections may produce an acute swelling of the sinus membranes (fig. 6), as has also been demonstrated by Dr. Proetz in allergic reactions.

When possible, the antrums are filled through the normal ostium by means of a double curved 16 gage steel cannula (4, fig. 7). As this method is impossible in a number of cases a straight 17 gage needle (5, fig. 7) is used high in the inferior meatus. The small gage of the cannula and needle prevents the dripping of oil when the syringe is refilled. Any syringe of less than 5 cc. capacity is rather unsatisfactory.

While filling, the number of cubic centimeters is counted to determine the volume of the sinus. If an antrum holds only from 3 to 5 cc., one can be reasonably sure that there is something in the antrum that is taking the space that would ordinarily be occupied by the oil. On the other hand, if an antrum holds from 14 to 20 cc. and even 30 cc., as occurred in one of my recent cases (fig. 8), then one can be rather certain that the antrum must be a fairly normal one to hold so much fluid (fig. 9).

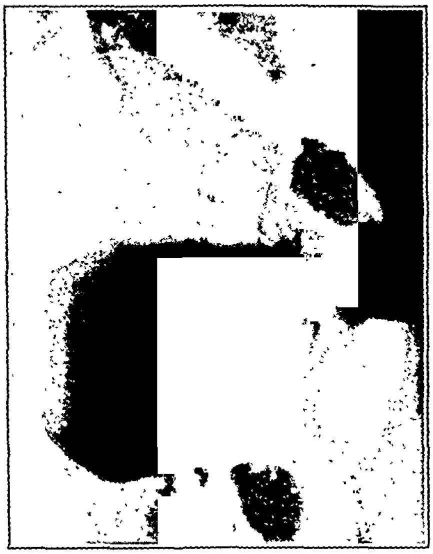

Fig. 8.—Side view of unusually large antrum in a male patient; capacity, 30 cc.

If a water solution is being used at a primary irrigation, I make it a practice to put the first of the solution in with a syringe and record the volume. Whether the antrum holds 3 cc. or 20 cc. is often an important diagnostic aid and may help to decide the course of further treatment or roentgen examination.

For direct filling of the frontal sinuses a small silver cannula with a Luer tip bent at right angles (2, fig. 7) is inserted. The patient is then placed in the knee-chest (fig. 10) or marked forward position (fig. 11) and the oil injected in one of these positions (fig. 12). Most frontal sinuses coming up for injection are obscure cases in which an anterior ethmoid or intranasal frontal operation has already been done. This greatly facilitates the insertion of the cannula.

When sinuses have been radically opened and require further study, the cavities may be packed with a thin strip of gauze soaked in full strength iodized poppyseed oil.

For the sphenoids, only one side should be done at a time to prevent overlapping shadows. Both antrums, however, may be injected at the same time as the anteroposterior views will usually show any defect and the lateral views, although overlapping, can be read.

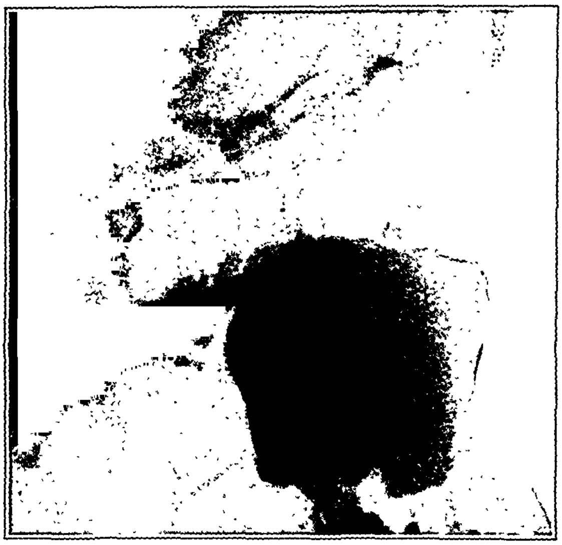

Fig. 9.—Side view of antrum in a male patient with history of a chronic bronchial cough; capacity, 24 cc. Both antrums held 24 cc. and did not show filling defects.

I have been experimenting with iodized poppy-seed oil (40 per cent), in cases of atrophic rhinitis. Everyone knows that iodine is not only a fair deodorant but seems to be rather effective in relieving dryness of the mucous membranes. Its combination with oil seems to lessen the disagreeable crusting.

The antrums are filled at intervals of one or two weeks with the iodized oil, which drains slowly into the nose. In some cases oil is evident on lavage two weeks after its instillation.

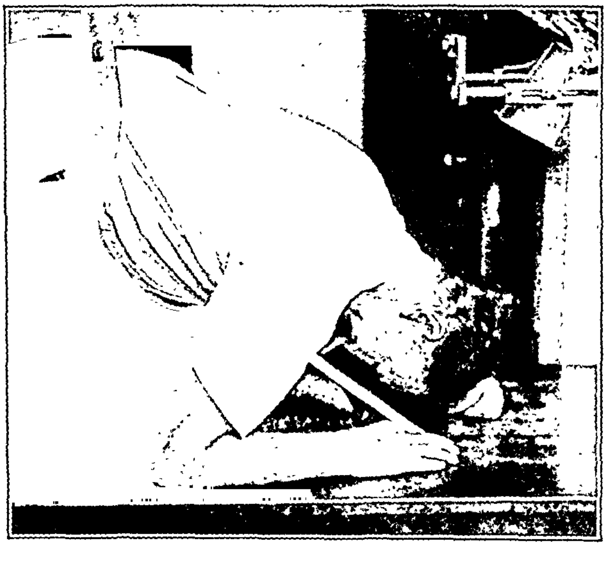

Fig. 10—Knee-chest position cannula (2, fig. 7) is first inserted and oil is injected through the right angle tip The x-ray plate is next to the forehead. In this position gravity prevents the oil from leaving the frontal sinus.

It is yet too early to comment on its real value in this troublesome disease.

CONCLUSIONS

1. The use of opaque or iodized oils is an important step beyond the simple roentgenogram.
2. Iodized oils can be used as a routine in the antrums, with little additional effort, and whenever roentgenograms are indicated.
3. Their use in other sinuses may be confined to obscure cases in which surgical intervention is contemplated.

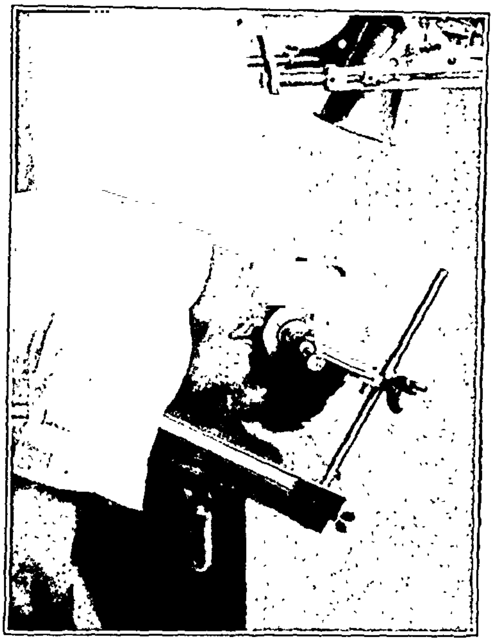

Fig. 11.—Patient sitting on a high stool with head bent well forward; filling as noted under figure 10.

4. For direct instillations, heavy petrolatum is used for dilutions to increase the viscosity.
5. Iodized poppy-seed oil, 40 per cent, diluted with two parts of heavy petrolatum, or iodized rape-seed oil diluted 50 per cent, and brominized sesame oil full strength constitute the opaque mediums of choice.
6. Iodized oils should be used immediately after irrigation or not at all for from seven to ten days, as swelling of the sinus membrane may follow within twelve to twenty-four hours after any irrigation.
7. Swelling of the sinus membranes may occur following an acute rhinitis, necessitating the delay of roentgen examination.
8. If water is being used as a primary irrigation, the first of the solution should be put in with a syringe and the volume recorded. Whether the antrum holds 3 cc. or 20 cc. is often an important diagnostic aid.
9. Frontal sinuses may be filled with the patient in the knee-chest position.
10. Sinuses previously opened may be studied by packing with a thin strip of gauze soaked in full strength iodized poppy-seed oil before roentgen examination.
11. Sphenoids should be injected on one side at a time to prevent overlapping shadows.
12. The two antrums may be injected at one time.
13. In atrophic rhinitis the antrums may be filled with full strength iodized poppy-seed oil, which seems to have a beneficial effect.
14. The use of stereoscopic views, with or without opaque oils, seems to offer some advantages.

559 Doctors' Building.

ABSTRACT OF DISCUSSION

Dr. Robert H. Fraser, Battle Creek, Mich.: While the author does not report on any examinations with the displacement or suffusion method, he has contributed greatly to the success of the injection method. I have made 1,200 observations, including 200 suffusions, and at present am making more suffusions of the anterior series in the prone position than injections. The advantages are the absence of intranasal manipulations of any kind. Regarding the incidence and importance of maxillary sinus disease as compared with ethmoidal disease, observers will differ. Chronic suppurative sinus cases are frequent in some practices, but in mine the mixed and hyperplastic sinus cases, involving many sinuses, with suppuration in perhaps some of them, are *the* problem and develop need for iodized oil. Hirsch's idea that the ethmoid is less commonly involved than the maxillary in the latter type of disease is not verified by American experience. In the majority of cases the maxillary sinus involvement comes late following ethmoid trouble, and the latter must receive attention along with the maxillary. The child with ethmoiditis should not be allowed to develop thickening in an antrum before many constitutional aids to recovery are applied. What membranes will swell and how much, as, for example, due to irrigation, is most interesting of all because more light is needed here. A thick membrane is not healthy. Traumatic swelling is about 3 mm. I have never seen a swelling in a really normal sinus due to a saline or an oil. Swelling due to allergy is more. Swelling due to transient bacterial infection is not great unless it is accompanied by chemical deficiency resulting in vasodilatation. Past disease, however, may leave fibrous membrane unable to swell even in response to trauma. If the sinus mucoperiosteum has been greatly swollen in the past, from the catarrhal type of disease of Hirsch and Zuckerhandl (hyperplastic, mixed), it can swell rapidly and to a high degree. A rapid swelling of 7 or 8 mm. means definitely that there is hyperplastic nasal disease in the constitutional tendency. A chart of the variations should be made and standardized. The history comes first, however, but must be studied in the light of an appreciation of the many oddities of these diseases and their constitutional connections.

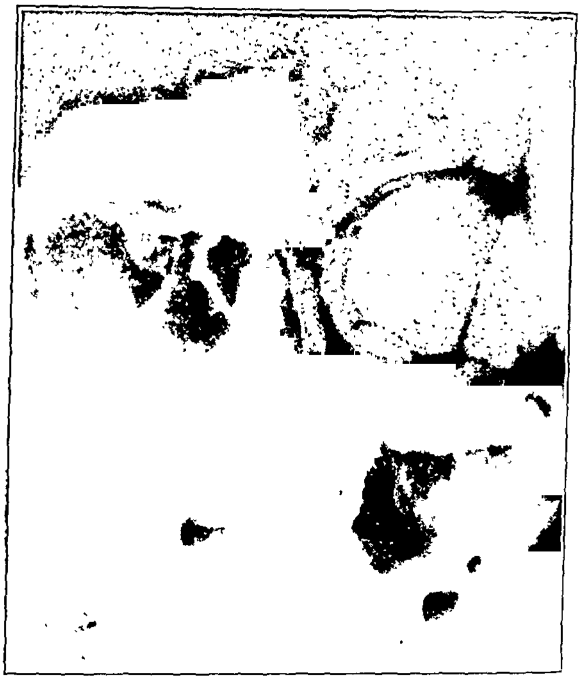

Fig. 12.—Chronically infected frontal sinus filled while patient was in the knee-chest position (fig. 10).

Dr. Samuel Iglauer, Cincinnati: I should like to mention one point in particular, and that is that not infrequently I have been disappointed after taking these pictures and opening the antrum in not finding what I had expected. At first I was inclined to believe that when I saw a filling defect in the antrum there must be a polyp or cyst present; but on operating several days later, on more than one occasion I found a practically normal mucosa or one slightly edematous. I think Dr. Proetz, who unfortunately is not here, has explained this phenomenon. He has found in a certain number of allergic patients that when he filled the antrum, or attempted to do so, during an attack of vasomotor rhinitis, he would get a filling defect, and if he waited a week or two and filled the same antrum it was of normal size and contour. I think that factor must be borne in mind, and one must be sure that one is not dealing with an allergic patient. I am sure Dr. Goodyear is to be congratulated on some new ideas that he has introduced. One is packing the middle meatus to prevent overflow into the nose; and the second is his method of filling the frontal sinus. I do not quite agree that he can explain the pathology of ethmoiditis as secondary to the maxillary infection. I feel that the pus would not flow from the antrum into the ethmoids because I do not believe the secretion would enter the ethmoids if they contained air, and the whole theory of Dr. Proetz's method is to exhaust the air from the ethmoids in order to enable him to fill the ethmoids with iodized oil.

DR. HENRY M. GOODYEAR, Cincinnati: I am glad Dr. Fraser has been using iodized oil in the ethmoids. It is rather easy to put oil into the antrum, and if the indications are such that one feels that roentgenograms of the patient's head should be made, it is not much work to insert oil into the antrum, and at least two sinuses have been ruled out to begin with.

SUPRARENAL CORTICAL INSUFFICIENCY AND CYTOTOXIC CONTRACTION OF THE SUPRARENALS [*]

OTTO SAPHIR, M.D.
AND
HERBERT F. BINSWANGER, M.D.
CHICAGO

A disease of the suprarenals exists which is even rarer than tuberculosis of the suprarenals and may cause a clinical syndrome closely resembling Addison's disease. This disease is most commonly spoken of as atrophy of the suprarenal glands.[1] Brenner[2] calls it atrophy of the cortex; Roessle,[3] inflammatory atrophy. The use of such terms as "essential adrenal insufficiency"[4] signifies that the nature of this disease is not fully understood. In reviewing the literature, one gains the impression that there are apparently two entirely different diseases of the suprarenals leading to end stages which, on superficial examination at least, are confusing. Kovacs[5] and more recently Omelskyj[6] have differentiated strictly between changes purely inflammatory in nature and primary degenerative changes leading to necrosis and disappearance of the cortical cells. The inflammatory lesions of the suprarenals involve both the cortex and the medulla and are often brought about by tuberculosis. But other nonspecific inflammations or thrombosis of the suprarenal vein may lead to similar pictures. The term "locally contracted suprarenals" (oertliche Schrumpfnebennieren) is used to denote such changes, implying that the contraction is due to local causes and is not brought about by a systemic disease acting on the suprarenals. Since these changes, however, are always inflammatory in origin, the term "inflammatory contracted suprarenals" is perhaps less open to misinterpretations than the term "locally contracted suprarenals." Clinically such a case might present itself as Addison's disease provided that both medulla and cortex are markedly destroyed.

When primary degenerative changes occur, these involve the cortical parenchyma only and lead to necrosis of cortical cells. This necrosis is accompanied by a lymphatic infiltration but without apparent scar formation. Since the cortex alone is affected in such cases, they do not give the clinical picture of the classic Addison's disease but should (according to Kovacs and Omelskyj) be classified as suprarenal cortical insufficiency clinically, while the term "cytotoxic contraction of the suprarenals" is used for the pathologic lesions. Two cases of this type are presented here, on which a distinction in the nomenclature and nature of this disease will be based.

CASE 1.—*Clinical Examination.*—A woman, aged 42, came to the hospital complaining of transitory headache for many years which progressively grew worse and became more frequent. During the last six months she had noticed that the color of the skin had changed to a brownish yellow tint. She further complained of intense nervousness, which first manifested itself about five months previously. For the preceding five weeks she had suffered from nausea and loss of appetite. Over a period of six months she had lost 9 pounds (4 Kg.). The physical examination was essentially negative. No neurologic lesions could be found. There was a moderate secondary anemia. During the first seventeen days of her stay in the hospital the most outstanding clinical symptoms were belching, nausea, frequent vomiting, headaches and poor appetite. Fourteen days before the patient died a gradually increasing weakness was noticed. At that time an incontinence of the urinary bladder developed. A few days before death the patient was irrational at intervals. The weakness became much more pronounced. The accompanying table is offered to show the various blood pressure readings.

Blood Pressure Readings in Case 1

Date	Blood Pressure	Date	Blood Pressure	Date	Blood Pressure	Date	Blood Pressure
9- 4	106/78	9- 4	94/70	9- 4	92/66	9-17	82/54
9-17	78/54	9-21	82/60	9-21	92/64	9-21	92/68
9-22	94/68	9-23	84/64	9-25	92/78	9-26	98/68
9-27	82/64	9-27*	104/70	9-28	94/70	10-1	90/70
10-3	84/60	10-4	84/63	10-5	106/78	10-6†	74/56

* After injection of epinephrine.
† Shortly before death.

The blood pressure varied from 74 systolic and 56 diastolic shortly before death to 106 systolic and 78 diastolic; the majority of readings were above 90 systolic. A chemical examination of the blood which was made during the first week of the hospitalization of the patient revealed 60 mg. of dextrose per hundred cubic centimeters and a nonprotein nitrogen content of 40 mg. The basal metabolic rate was—8.2. Six weeks after admission the patient relapsed into coma and died. The clinical diagnosis was Addison's disease.

Pathologic Examination.—The autopsy was performed about two hours after death. The body was well developed but poorly nourished. The skin had a brownish, bronzelike appearance. The pigmentation was most marked about the abdomen, back, buttocks and thighs. The lymph nodes throughout the body were enlarged. They were soft in consistency and showed on cut section simple hyperplasia The serous cavities presented no abnormalities The lungs were the seat of a moderate emphysema. There were a few consolidated portions throughout both bases. The heart was small and weighed 220 Gm. The liver, kidneys and spleen were essentially normal. The gastro-intestinal tract showed no changes. The brain was anemic, but neither gross nor histologic lesions were demonstrable. Both ovaries were of about normal size. On section they offered a few small cystic spaces containing clear, amber fluid. Tubes and uterus were normal. The thyroid was somewhat smaller than normal, of firm consistency, and showed a smooth surface. On cut section many minute colloid granules were seen throughout. The parathyroids appeared normal. The thymus could not be found. It was replaced by fat tissue. The hypophysis was normal in size and shape. There were no signs of inflammation or tumor. The pineal body showed a few calcified granules; otherwise there were no changes. Both suprarenals were very small but of about normal consistency. The left suprarenal weighed 2 Gm. The thickest portion measured 2 mm. in diameter. The capsule was thin and gray. Grossly, no intact cortical tissue was recognizable. The capsule seemed to enclose only the medulla. A few places showed on cut section bright yellow dots and streaks indicating remnants of cortical tissue. The right suprarenal weighed 3 Gm., the thickest portion measuring about 3 mm. in diameter. The cut section showed a yellowish, interrupted circle barely visible between the capsule and the medulla. The medulla of both suprarenals was reddish gray but no gross changes were demonstrable. No accessory suprarenals were found.

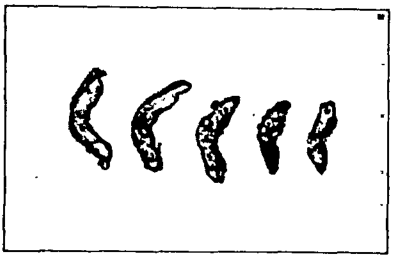

Fig. 1 (case 1).—The left suprarenal, natural size.

Histologic Examination.—Both suprarenals were cut into twelve blocks; ten blocks were preserved in a diluted "solution of formaldehyde-U. S. P." (1:10), and two in alcohol. Hematoxylin-eosin sections of the left suprarenal showed in some of the fields the capsule and medulla without any recognizable cortex. Some of the sections revealed a few very large cortical cells with a light stained cytoplasm and an eccentrically situated vesicular nucleus. Some of these cells were twice or three times as large as normal cortical cells. The cells were separated by a lymphocytic infiltration and a few stroma fibers consisting mainly of walls of small capillaries. Other fields offered only one or two large cortical cells, while others again showed several of them arranged into small groups. In some of these groups the cells assumed the form of small cords. These groups seemed regenerated islets of cortical tissue. None of the sections, however, showed the arrangement into the typical three different layers of the normal cortex. Some of the cells contained a varying amount of a yellowish pigment, while others did not show any trace of pigmentation. Most of them were the seat of a marked cloudy swelling and vacuolar degeneration. The boundaries of many cells appeared very indistinct. Some cells showed no nuclear staining. A small amount of connective tissue was found throughout the cortex combined with a lymphocytic infiltration, but there was no actual scar formation. However, it is more likely that the stroma merely appeared denser because of the loss of the parenchyma and because of the fact that the blood capillaries were drawn closer together. Many distended blood vessels were seen. The medulla appeared smaller than normal and showed a few lymphocytes scattered throughout but otherwise no changes.

Sections that were stained according to van Gieson's method showed many connective tissue fibers throughout the capsule, while the cortex contained only a moderate number of fibers. With the aid of an elastic tissue stain (Orcein), the differentiation between cortex and medulla could easily be made out, the latter containing a network of many elastic fibers. The presence of elastic fibers in the normal medulla was especially emphasized by Kovacs. In frozen sections, which were stained with sudan III, many fat globules were demonstrable throughout the cortical cells. Unfortunately the suprarenals were not hardened in chromic formaldehyde immediately. The chromic reaction, therefore, did not give very good results. The affinity of the medullary cells to basic stains, however, was easily demonstrable.

The right suprarenal showed practically the same changes. There were more cortical elements present in the form of regenerated islets surrounded by a lymphocytic infiltration. But most of these cells were of foamy cytoplasm and apparently degenerated. A few fields showed, in addition to lymphocytes, blood corpuscles within the tissue. The medulla was of the same appearance as that of the left suprarenal.

Sections of the thyroid presented many atrophic follicles. An abundant amount of lymphocytes was found throughout the slides. Sections of the lymph nodes showed a pronounced simple hyperplasia. The remainder of the organs showed no histologic changes of note.

Summarizing the gross and microscopic observations, we have described a case in which there was a marked diminution in the size of the suprarenal glands caused by an almost complete absence of the cortical structures with a relatively well preserved medulla. Aside from this, the only other changes noted were a generalized hyperplasia of the lymphatic apparatus and a moderate degree of atrophy of the thyroid gland. The histologic examination of the suprarenals revealed as the main lesion an almost complete disappearance of the cortical parenchyma, while the supporting stroma and blood vessels remained unchanged. There was no scar tissue nor any other evidence of chronic inflammatory changes. The lesions were found bilaterally. Some regeneration of the cortical cells was evident. These regenerated cells were larger than normal but did not show the characteristic arrangement into the three different layers found in normal suprarenals. These regenerating cells also seemed damaged, as indicated by the marked cloudy swelling and vacuolar degeneration. Whatever had caused the changes resulted in a specific and selected destruction of the cortical cells.

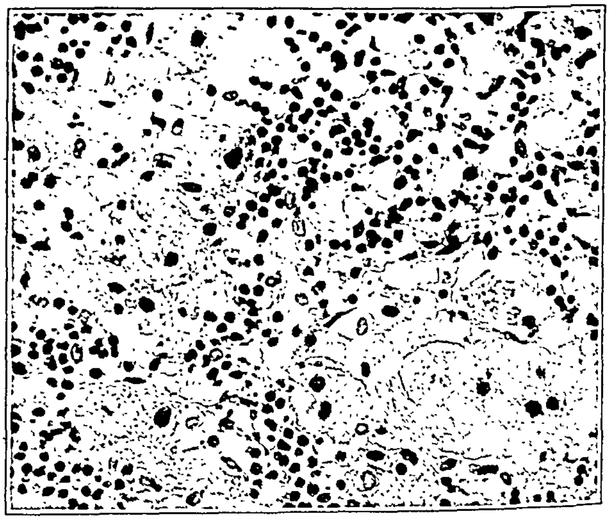

Fig. 2 (case 1).—Cortex of suprarenal: remnants of large regenerated cortical cells; lymphocytic infiltration without new formation of connective tissue: iron hematoxylin-eosin preparation; × 260.

Kovacs believes that the cortical cells are destroyed by a specific toxin, a cytotoxin in his opinion, whose nature is obscure but which may be liberated by abnormal metabolism rather than an infectious disease. The toxin is carried to the suprarenals by the blood stream, leading to mandatory involvement of both suprarenals. The progressive nature of this disease, which is shown by the degenerative remnants of regenerated cortical cells and by the final death of the patient, indicates that the cytotoxin is liberated either continuously or at intervals over an appreciable period of time. At present it is not known under what pathologic conditions such cytotoxins are formed.

The bilateral involvement of the suprarenals in this case, the selected destruction of the cortex combined with apparently normal medulla, and the absence of scar formation in the suprarenals fulfill the requirements of Kovacs, and the case, therefore, falls in the classification of cytotoxic contraction of the suprarenals.

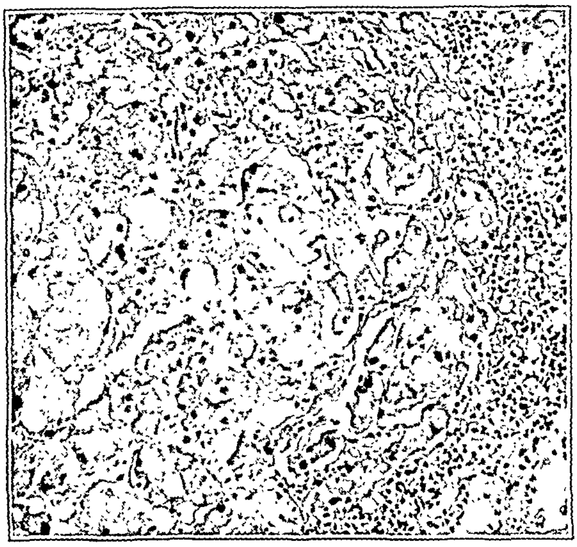

Fig. 3 (case 1).—Cortex of suprarenal: groups of degenerated cortical cells without the characteristic arrangement; iron hematoxylin-eosin preparation; × 120

Marine[7] has raised the question whether the changes of the suprarenal cortex of these cases are similar to the ones found in the thyroid in exophthalmic goiter. It might be possible, in his opinion, that these changes signify a state of exhaustion of the suprarenal cortex which must have been preceded by a state of overactivity.

Clinically, the patient presented some features that were characteristic of Addison's disease; namely, the bronze skin and gastro-intestinal disturbances. The asthenia, so characteristic of Addison's disease, developed late, apparently during the hospitalization of the patient but was not obtained in the anamnesis. The blood pressure, even though low, yet reaching 106 systolic, 78 diastolic, was not quite low enough to be typical of Addison's disease. Kovacs and Omelskyj emphasize that in clinical cases of Addison's disease both cortex and medulla are involved. They classify their cases as insufficiency of the suprarenal cortex in preference to Addison's disease because the characteristic low blood pressure and asthenia were not present. It is a question whether our case could not, for the same reasons, be classified clinically as cortical insufficiency of the suprarenals in contradistinction to Addison's disease. At the present time this question cannot be settled. Cases such as the one reported are rare and many of them have an insufficient clinical history and few blood pressure readings, which makes it difficult to analyze them. Even in Kovacs' case detailed clinical observations are lacking, and only one blood pressure determination is recorded.

Animal experiments[8] showed that the cortex of the suprarenal is indispensable to life while the medulla can be destroyed without apparent harm to the animal. Rogoff and Dominguez[9] have shown that after bilateral suprarenalectomy the blood pressure is not affected. These facts make it difficult at first to understand why, as Kovacs and Omelskyj maintain, the typical Addison's disease has its pathologic equivalent in destruction of both cortex and medulla. One should, however, guard against drawing too close a parallel between an acute animal experiment and pathologic changes which are end-stages of chronic lesions, especially since the typical Addison's disease cannot as yet be produced experimentally. Only exact clinical observations combined with close correlation of the autopsy observations may make it possible in the future to distinguish clinically between cortical insufficiency of the suprarenals, which often has its pathologic equivalent in cytotoxic contraction of the suprarenal cortex, and Addison's disease. In cases, therefore, which present themselves clinically not as pure Addison's disease, and which show as the [illegible] only pigmentation and gastro-[illegible], one should at least consider the possibility of cortical suprarenal insufficiency occurring as a result of cytotoxic contraction of the suprarenals.

CASE 2.[10]—*Clinical Examination.*—A white woman, aged 36, was admitted to the hospital with the complaint of nausea and of pain on the right side. The pain came on suddenly, had persisted one day, and began to radiate all over the abdomen. The patient had had three similar attacks but none was quite as severe as the present one. She always had been well and had not suffered from gastro-intestinal disturbances or weakness.

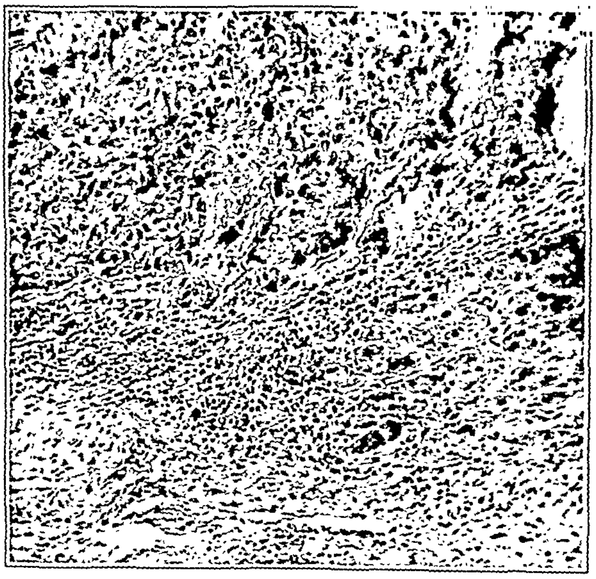

Fig. 4 (case 2).—Cortex and medulla: small groups of old cortical cells, lymphocytic infiltration throughout the cortex, and apparent normal medulla; iron hematoxylin-eosin preparation; × 120.

The physical examination revealed a peculiar bronze color of the skin which, as the patient stated, had been present for some time. She could not state exactly how long ago the pigmentation developed. The only important clinical observation was a tenderness in the right lower quadrant with some rigidity. The blood pressure reading on admission was 110 systolic and 60 diastolic. The clinical diagnosis was appendicitis. An appendectomy was performed the same day, with the use of ethylene as an anesthetic. The operation was uneventful. The appendix was small and adherent to the broad ligament. Histologically it was the seat of a chronic obliterative appendicitis.

[10] We are indebted to Dr. Carl Henry Davis of Milwaukee and to Dr. William Thalhimer for the data in this case.

Two days after operation the patient became stuporous and lethargic and voided only a small amount of urine. Four days after the operation, she began to talk irrationally, lapsed into unconsciousness and died shortly afterward.

Pathologic Examination.—The body was poorly nourished but well developed. The bronze color was noted throughout the skin, especially on the face. The field of operation showed no acute inflammatory changes. There was no evidence of peritonitis. The heart and lungs were normal. The visceral organs appeared free from pathologic changes. The lymph nodes throughout the body were enlarged and soft in consistency. On cut section they showed a simple hyperplasia. Neither suprarenal, at first, could be found. An extensive search, however, revealed a small mass of tissue in both retroperitoneal regions above the kidneys, still showing the shape of suprarenals. No accessory suprarenals could be found.

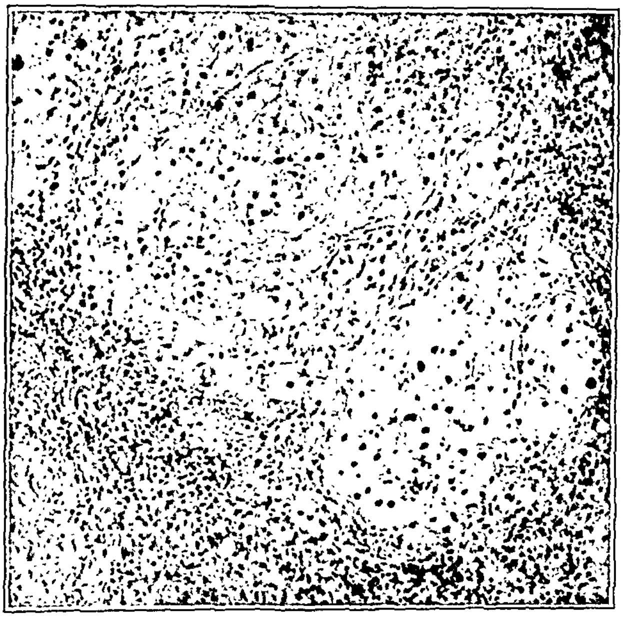

Fig. 5 (case 2).—Cortex and medulla: large regenerated islets of cortical cells; iron hematoxylin-eosin preparation; × 120.

The histologic examination of the small mass of tissue found above the kidneys revealed suprarenal structures. Hematoxylin-eosin preparations showed throughout the cortex large nodular areas consisting of an apparent new formation of cortical cells. These cells were very large and showed in part small cordlike structures and in part no particular arrangement. Their cytoplasm was markedly granular in appearance. Some of the cells contained large vacuoles throughout the cytoplasm while others had varying amounts of a brownish pigment. Many of the cells were faintly stained, showing the cellular outlines indistinctly, but the coherence of the cells could still be made out. All of the nodular areas were close together with hardly any dividing stroma. Only occasionally cells were found in groups of four or five with a moderate amount of stroma between them. Some of the sections showed a few lymphocytes and large phagocytic cells. There was no connective tissue or any hyaline material or scar tissue. The normal arrangement of cortical cells in three different layers could not be made out. The medulla was normal in size. The medullary cells were large and apparently unchanged. Few lymphocytes were seen in the outer portions of the medulla close to the cortex. The chromophil reaction could not be obtained because the tissue was hardened in formaldehyde. The affinity of the medullary cells to basic stains, however, was clearly demonstrable. Outside of small blood vessels, throughout the cortex and medulla, a moderate number of red blood cells were seen. The fat stain (sudan III) showed a large amount of lipoids in the cortical cells. The capsule was fibrosed but showed only an inconspicuous lymphocytic infiltration.

The second case showed the disappearance of the normal suprarenal cortex with marked regeneration of the cortical cells assuming the forms of nodules; but most of the cells were the seat of marked degenerative lesions and necrosis. The medulla apparently was not affected. Throughout the cortex a few lymphocytes were found. Following Kovacs' classification, we must consider the changes as typical of cytotoxic contraction of the suprarenals.

If we compare the microcopic observations in the two cases it is evident that the changes of both suprarenals are essentially identical. In the first case, however, the changes were much more marked. Many fields showed only a few remnants of cortical cells which were separated from one another by a stroma showing dilated vessels and a lymphocytic infiltration. There was evidence of regeneration but many fields revealed only remnants of regenerated islets of cortical cells. The second case showed much more cortical tissue. There were many more large regenerated islets of cortical cells, many of which still showed the cell outlines clearly and were connected with other cells. The histologic picture of both suprarenals explains why the first case with far advanced lesions in the suprarenal cortex gave a clinical picture which could be interpreted as chronic insufficiency of the suprarenal cortex and why the second case with less severe lesions in the cortex showed, up to a few days before death, no clinical symptoms of suprarenal insufficiency with the exception of pigmentation.

Clinically, case 2 is interesting because of the sudden death shortly after appendectomy in an apparently healthy person. The autopsy revealed that death was due to the changes in the suprarenals. The only clinical observation that could be brought into correlation to these lesions was the pigmentation of the patient. No accurate data as to the duration of the pigmentation were obtained. Furthermore, no attempts were made to ask specifically for signs of asthenia. Nausea, of which the patient complained, was referred clinically to inflammatory changes of the appendix. It was pointed out in the anamnesis that the nausea developed only one day before the patient was admitted to the hospital. The blood pressure just before the appendectomy was 110 systolic and 60 diastolic. It is, however, fair to assume that neither asthenia nor gastro-intestinal disturbances, if at all present, were marked because otherwise they would have been easily obtained in the case history. The marked regeneration of the cortex and the surviving old cortical and medullary cells prevented the appearance of clinical signs of suprarenal insufficiency, with the exception of the skin pigmentation. It seems, however, as if following the operation the remnants of cortical tissue became insufficient, as indicated by the marked cloudy swelling and vacuolar degeneration of the cortical cells.

According to Marañon, "the prognosis and duration of Addison's disease depends on the appearance of the pigmentation. If the latter is an early symptom, the duration is long and the prognosis seems relatively

---

[11] Marañon, G.: L'insuffisance surrénale primitive et secondaire, Rev. franç. d'endocrinol. 6: 277 (Aug.) 1928.

good. Our case showed pigmentation as the only clinical evidence of lesions of the suprarenals. If one may assume, from the histologic picture, that eventually there would have developed other symptoms of Addison's disease or of chronic cortical insufficiency, then the early pigmentation would point to a long duration and good prognosis.

Cases of sudden death following operation which show at the autopsy table marked destruction of the suprarenals are rare but do occur. Hornowsky[12] reported two cases falling in this group. One of the patients dying shortly on removal of carcinomatous nodes in the inguinal region showed both suprarenals consisting almost entirely of scar tissue. The patient had never shown symptoms of Addison's disease. Zimmerman[13] published reports of two cases of sudden death following cesarean operation. Both cases showed at the autopsy a marked atrophy of the suprarenal medulla. Whether or not the cortex was also involved in Zimmerman's cases cannot be stated because of the complete lack of histologic description and diagnosis. Huebschmann[14] described a patient who was apparently in perfect health and who suddenly became unconscious and died the same day. At the autopsy a brownish color of the skin and buccal membranes was noted. Both suprarenals were much smaller than normal and had a granular surface. Histologically they showed marked atrophy with some inflammatory changes. Marchand[15] reported a case of sudden death after an operation for perityphlitis. The patient, who had had no clinical symptoms of Addison's disease, showed at autopsy a complete caseation of both suprarenals. Omelskyj also mentions that marked changes of the suprarenals might remain clinically silent until they give rise to a sudden illness leading to death a few days afterward.

The death of our patient, which must be interpreted clinically as the result of suprarenal insufficiency, was apparently brought about by the severe degeneration of the remaining cortical cells. Whether the demand for the secretion of the suprarenal cortical cells after the operation was too great or whether the operation itself was responsible for the sudden loss of function of the suprarenal cortical cells cannot be decided. In the final analysis, we believed that the death was due to acute cortical insufficiency. It was pointed out previously that the cloudy swelling and vacuolar degeneration was very pronounced throughout the cortical cells. Not taking into consideration the physiologic importance of the cortex but merely considering the histologic changes, we believe that this case should be classified clinically as one of acute cortical insufficiency of the suprarenals which pathologically showed changes characteristic of early cytotoxic contraction of the suprarenals.

SUMMARY

A clinical and pathological study of two cases of suprarenal cortical insufficiency was made. One case, clinically diagnosed as Addison's disease, showed changes which histologically are similar to the ones found in cytotoxic contraction of the suprarenals (Kovacs). An analysis of this case revealed that the blood pressure reached 106 systolic and 78 diastolic and that the asthenia developed only shortly before the patient died. A possible clinical differentiation between Addison's disease and cortical insufficiency of the suprarenals may be made. The second patient, who died shortly after an appendectomy, showed similar lesions but much less marked. There were severe degenerative changes throughout regenerated cortical cells. Clinically, the only symptom that could be referred to suprarenal lesions was a diffuse pigmentation of long duration. The sudden death of the patient was attributed to an acute incompetence of the regenerated cortical cells following the operation.

SPECIAL PSYCHIATRIC PROBLEMS IN CHILDHOOD *

ESTHER L. RICHARDS, M.D.
BALTIMORE

First of all I should like to restate the topic for discussion as "To whom does the health of childhood belong?" The separation of mental health and physical health is a residual of that dark age in the history of medicine when a human organism was divided quite neatly into mind and body. Mind and soul were considered to be the concern of teacher and clergy; body—or everything below the eyebrows—belonged to the physician. It has taken the medical profession decades to realize that a human being functions not in segments of mind and body but as a finely integrated organism; that every instinct and its accompanying emotion affects every cell in the body, making blood circulate faster or slower, gastric juice increase or decrease, glands of internal secretion function or dysfunction. Internal medicine now makes the statement that at least 40 per cent of men and women who consult physicians for a wealth of distressing bodily sensations are victims of poor health associated with unwholesome states of mind. How do they get into this condition? The answer is in every instance an individual one based not on the precipitating factor of a romantic misadventure or a financial loss but on lifelong poor habits of meeting strains—emotional, intellectual, physiologic. In the study and treatment of this large percentage of adults in poor states of health, the internist has been driven inevitably back to the childhood story of these patients, asking himself again and again whether a better start in life would have averted the grown-up discomfort. By virtue of the same spirit of intelligent inquiry into the hygienic possibilities of the first ten years of life the profession is conducting an increasingly successful campaign against bony deformities, cardiac disease, tuberculosis and syphilis. Hygiene, then, as the science of health must concern itself with every factor contributing to the growth, development and personal welfare of a human being. Mental hygiene is an aspect of hygiene that takes a genetic interest in the behavior of an individual, dealing with assets and liabilities of life which may or may not develop into pathologic behavior. With this formulation of mental hygiene it would seem that the mental health of childhood belongs to no one group of society or branch of departmental knowledge. The mental health of childhood should be the active concern and intelligent interest of physician, teacher, parent, psychologist, clergyman, psychiatrist, social worker, public health nurse, and every other constructive force of the social organization that comes in contact with the welfare of children.

MENTAL HEALTH OF CHILDHOOD

This view of mental hygiene and its place in the field of child health is, I realize, quite at variance with ideas about the subject held by all sorts of professional people. Dr. Crothers has kindly put at my disposal letters from some 250 pediatricians, psychiatrists and psychologists of note in different parts of this country to whom he propounded the question being discussed today. In reading these replies one is reminded of a remark of Margaret Fuller, that famous New England iconoclast of the seventies, who once said in a lucid moment, "I don't know where I'm going. Follow me." The usual psychologist's idea of the mental health of childhood has been admirably set forth by Dr. Anderson:

> Mental hygiene lies predominately in the field of education rather than in the field of either psychology or medicine since the primary purpose of education is to prepare individuals to meet the problems of life. While education should receive all the assistance it can from both psychology and psychiatry, nevertheless it is the discipline which has been set up by society for the training of individuals and which has both the prestige and the historical background for work in this field. It does not seem to me that society can or will establish a separate discipline independent of the schools for the training of the general run of individuals. Psychiatry will continue to deal with abnormal individuals. In psychiatry, in contrast with psychology, the primary emphasis is placed upon the treatment and care of the individual who deviates to a marked degree from his fellow men. Any science considering abnormal phenomena is very largely based upon a study of individual cases or variations from the normal rather than upon basic or common trends. . . . The control of mental hygiene is not now in medical hands, nor will it ever be . . . . To say that physicians are to assume complete control of the mental hygiene field is to say that physicians are going to control society. It seems to me that the interests of the physician in the field should be scientific rather than propagandistic, and that his purpose should be to formulate correct data and principles rather than to embark on a general mission of the propagation of a faith.

Evidently in the mind of the psychologist the mental health of the child is synonymous with the intellectual ability of the child, and education is considered as an intellectual discipline. The failure of the child to measure up to this discipline is considered an educational matter. As a matter of fact, the more childhood is studied in an attempt to interpret behavior rather than to judge conduct, the more convincing it is that the mind of the child is the whole expressive activity of the child. Behavior, or mind, includes not only the intellectual faculties—memory, reasoning, judgment—but a wide range of other activities—emotions, cravings, desires, instincts, composed partly of inborn tendencies and partly of habits of thinking and feeling and acting acquired from training and environmental influences. The busy teacher of a crowded classroom has little time to talk with parents, and she has no ambassador to send into the home. When school nurses are in the ratio of one nurse to every 3,000 school children in cities of more than 30,000 population, teachers cannot count on the help of school nurses in interpreting the behavior problems of the classroom. Consequently the teacher is obliged to deal with the restless, irritable, explosive, stealing child as an offender rather than as a maladjusted or misfitting individual. That is, she is obliged to use in treatment the trial and error method of finding something that will stop the annoying behavior—scolding, keeping in at recess, sending home or to the principal's office. If these methods do not work, the child is apt to be called incorrigible. In other words, education as a discipline treats the offense (or delinquency), not the offender (or the delinquent). Teacher, parent, physician, psychologist, social worker and school nurse need to get into the habit of thinking of a child's misfitting or maladjustment as a symptom of a wide range of causal factors. These causal factors go far beyond the realm of education as a discipline. They go into the home with its economic strains, its social strivings, its harmonies and disharmonies of parental relationships; they go into the neighborhood and its opportunities for recreation and social contacts; they go into the office of the family physician and his associations with the intimacies of family life. Child health and its behavioristic aspects projected against such a background of matters for consideration makes it impossible, it seems to me, to think of mental hygiene as "propaganda" and "a faith," or "a separate discipline to be set up by society independent of schools to train individuals." The more frequently one thinks of behavior as an aspect of health, and health as a component of behavior, the slower one will be to divide human beings simply into normal and abnormal, consigning the latter to one sphere of departmental knowledge. It is as reasonable to claim that the physician who treats disease cannot intelligently study genetic aspects of health as to maintain that the psychiatrist's province is only that of abnormal individuals.

The pediatrician's concepts of mental hygiene as indicated by the questions sent out by Dr. Crothers seem to indicate two general views as held by what might be called the nonprogressive and the progressive group of practitioners. The former feels that it has been paying enough attention to the mental health of childhood, and that the mental hygiene movement is a passing fad with which it does not wish to have any alliance. To this group of physicians mental health of childhood concerns itself chiefly with whether the child is feebleminded. As one physician puts it, "Entirely too much fuss is being made about defective children. I've always recognized them. Nobody can cure them." Then there are the stock phrases and stock prescriptions for "nervous" children. "Wait till puberty and she'll outgrow it." "He's a nervous, high-strung boy. Take him out of school for a year or two. Don't cross him."

The progressive group of pediatricians realizes that the mental hygiene movement aims to study the behavioristic growth and development of a child in the same intelligent manner that preventive medicine is studying his nutrition and metabolism. But progressive pediatrics finds itself a bit puzzled concerning how to go about this thing, and who shall do it. It asks whether mental hygiene is an attitude of mind or a technic. If it is a technic, should another technician be added to the office staff or should the child be sent to a psychologist or psychiatrist for treatment? Is there something so complex and mysterious about the mental health of childhood that a psychiatrically intelligent physician with an honest interest in the matter could not handle it? The answering of these questions is not easy because of just such unfortunate disagreements as I have referred to as existing between authorities in the branches of science devoted to the study of behavior. Not only do psychology and psychiatry disagree as to their respective provinces in the field of behavior, but there are various schools of psychology and schools of psychiatry so insistent on featuring some one ingredient of behavior that the larger issue of the behavior problem of the individual child becomes almost obscure. Mental hygiene is not a technic with which the pediatrician can equip his office like x-rays and basal metabolism. It is an attitude of mind that takes a genetic interest in the behavior of a child, for example, with reference to its constitutional endowment (biologic and psychologic) and what will be apt to give native endowment its best chance of development.

Such an attitude of mind calls for several prerequisites: First, it necessitates willingness on the part of the physician to have time and patience to talk with mothers and often fathers about the setting of home and school in which any given behavior problem occurs. From time immemorial physicians have done this, and even in this period of busy specialization some of the best mental hygiene I know of is daily practiced by pediatricians. Second, granted an honest desire to understand the patient better, is needed a knowledge of some of the practical causes of individual childhood misfitting that result in varying degrees of poor mental health beginning in childhood and going on through adolescence, frequently culminating in all sorts of nervous instabilities in maturity.

COMMON CAUSES OF CHILDHOOD MISFITTING

Among the strains commonly responsible for so-called badness and nervousness in children are the following:

1. Discrepancy between the child's intellectual ability to grasp and correlate the demands of home environment and school program with what home and school expect of a child of his age is a common cause of childhood misfitting. It can be discovered by the frequent and wise use of the Binet-Simon intelligence test and educational group tests that estimate whether a child is able to do the grade work to which he is assigned. The day is past when parent, teacher or physician can say offhand to a lagging boy or girl, "You could do it if you only tried hard enough." Psychologic science can estimate with a reasonable degree of certainty whether this child can or cannot accomplish what is expected of him. Unfortunately, our educational discipline does not adequately weed these children out and provide programs suitable for their limitations. These mentally retarded boys and girls get into junior high school and even further, and go to pieces trying to do sixth, seventh and eighth grade work with the intellectual equipment of 9 or 10 years. Now, a child who is forced to follow a program beyond his intellectual ability is bound to react with "nerves" or truancy, or stealing, just as a foot shod with an ill fitting shoe develops pathologic conditions of skin and joints. If a child's body is healthy the average medical mind leaves school placement to education, forgetting that educational mismanagement can occur in even the best of private schools. It is this 25 per cent of mentally retarded school children who, growing to adolescence and maturity, clog the wheels of dispensaries, juvenile courts, correctional institutions, and social agencies dealing with chronic dependence.

2. A child suffering from physical conditions seriously affecting nutrition, locomotion, eyesight, hearing or speech is recognized by all as behavioristically handicapped, but here again are mental hygiene problems that involve something more than making allowances for the disability. There is the tendency to progressive sensitiveness, the feeling of discouragement over tedious processes of treatment and inadequate opportunities for schooling, and always the increasing realization that he must be limited in what he can do for a livelihood and must be content to accept any remuneration for services that society sees fit to offer him. Psychology teaches that the physically handicapped person is poor reconstructive material because he is lazy and has no ambition. How much of it is due to the way he is treated?

3. A poor start in habit training during preschool years is another common cause of so-called bad and nervous children. No other member of society has such a good chance to start young mothers right in one of the most important features of mental health as does the physician. Regularity of food and sleep and excretory habits is of great importance, but equally so is the establishment of good habits of managing the emotions of fear and anger, the desire to be the center of attention, the cry to get what one wants. How often one hears the mother of a primary school child say, "You see I've always let him have his own way, because my doctor said he was a temperamental child and we must not cross him." She may be misrepresenting the doctor, and yet one meets not infrequently a colleague who has told the parents of an intelligent 13-year-old boy who has been stealing since he was 8 years old that they must not make an attempt to correct the habit because John Jr. is suffering from a polyglandular disturbance of which the Johns Hopkins pediatrics department fails to discover a trace. Or one meets another colleague bringing a tantrum-throwing, breath-holding girl of 5 with the story that this is the one mysterious case in which he has not been able to cure these characteristics by supplying sufficient calcium to the organism. Nursery schools, habit clinics and prekindergartens throughout the country are doing their best to give parents education in starting infancy and early childhood with a wholesome set of habits of emotional control. It does seem a pity that their influence is counteracted by many a physician who considers all this "the bunk."

4. Another source of individual childhood strain is to be found in unwholesome social conditions (economic strains, overcrowded living arrangements, broken homes, parental disharmonies, discrepancy between parental ambitions and child capacities). Here are matters that one accepts in theory, and yet fails so often properly to evaluate in given child cases. Getting at these facts takes time and patience and tactful questioning of child and mother. When facts are elicited, their treatment lies in how much parents are able to grasp and how much they are willing to accept. It is one thing to get them to carry out medical treatment of sun baths and diet; it is another to get them to modify their attitudes toward each other and toward life for the sake of a child who is suffering from such things.

A 12-year-old girl in whom the physical examination was persistently negative except for a marked degree of visceroptosis offers a case in illustration. She had had an appendectomy six months before and she complained of fatigue and lack of appetite. The physician advised her staying out of school for a year. Four months later she opened a telegram for her mother announcing the death of an aunt. The mother collapsed at the news; the child began to tremble and cry, and then vomiting started. Obviously there is much more to this family situation than meets the eye. The getting of this child to retain food, to gain in weight, and to get out of bed is simple compared with the treatment of the family situation to which she must return. Why should this child break down and her sister remain untouched by the domestic strain? Here is a child who has a temperamental endowment of such a nature as to predispose her to a serious break like this. She has always been quiet and contained and has never expressed an emotion of fear or like or dislike.

5. The temperamental equipment of childhood is a matter that we can all do well to study and not so often take for granted. Study of the adult breaking down nervously in later life is teaching us a great deal about childhood personalities that stand strains of life poorly and well. There is what is called the neuropathic constitution—an individual with good intellectual equipment and no disease of body, but with an organism whose nervous system seems put together the wrong way—autonomically speaking. Enuresis, night terrors, eczema, stammering, easy vomiting and tics are childhood forerunners of hay-fever, bronchial asthma, mucous colitis, angioneurotic edema of adolescence and maturity that are struggled with so unsuccessfully. Here are children who fatigue easily and yet have abundant energy. Teacher and parents tend to feature their precociousness and advise skipping grades and study in summer school for advanced credit, adding music lessons and a strenuous summer camp to a year overcharged with activity.

Another unfortunate temperamental equipment is that of the odd, quiet, seclusive, stand-offish, day-dreaming child who prefers staying by himself to playing in a group, who is always near when mother and teacher call, who takes criticism much to heart and broods over it. Previous generations cultivated these shut-in traits as ideal behavior patterns. Today we worry about them, realizing that the frank, active, out-going child who gets things out of his system has a far better chance to adapt himself to life's difficulties than his good, docile brother who never lies or steals or is impertinent to anybody.

6. An important aspect of the mental hygiene of childhood has to do with planning for energy outlets in the form of group play and well directed recreation. Society in its evaluation of attitudes toward play has gone through two periods: first, that of realizing that leisure time is a necessity for the maintenance of a healthy and well balanced life; and, second, that of recognizing the wealth of constructive educational possibilities associated with play and physical training. Year by year the physician is confronted by an increasing number of patients who break down under the strain of life. There is no big worry behind the picture of poor mental health, but in studying the individual stories of these patients one comes on lifelong inability to relax. The present age is not trying to repress the energy of childhood but to cultivate it, and in the cultivation to divert it into wholesome channels of activity. A person lives as a grown-up in a world with other persons, and his success or failure depends largely on his ability not only to get along with other people but also to enjoy group contacts.

ADEQUATE ENERGY OUTLETS FOR CHILDHOOD

It is agreed by all that "he that is slow to anger is better than the mighty, and he that ruleth his spirit is better than he that taketh a city." But it is one thing to treasure this proverb in the archives of memory; it is quite another to practice it in the traffic jams of daily experience. The boy or girl who has learned to do this on the playground will invariably put these principles into use in the business and social relationships of life. This thing is called team-work—the ability of a person to submerge his individualism for the good of the group. Power of good adjustment to life must come out of the experience of self-directed thinking, and it is this that formal education of home and school has been in the past so reluctant to permit. Sound physical education has made this its goal and watchword. By virtue of this it is coming to occupy an increasingly prominent place among the socializing institutions of the community. Ten years ago the physician and teacher struggling to plan for a mischievous, energetic half-grown boy could turn only to a barren yard, or acres of "keep off the grass." Today in the cities and in many towns every child and adolescent has a reasonable opportunity to play a game under the kindly supervising influence of men and women adequately equipped to teach fair play and the spirit of good sportsmanship.

There is another aspect of great importance in this matter of adequate energy outlets for childhood, and that is that play and recreation which satisfy serve to absorb a great deal of that restlessness and experimenting which arise from sex instinct and urges. Here is a topic of human behavior that has grown to be thought of as conduct to be judged rather than as behavior to be interpreted.

When does the sex instinct begin to show itself? For a child to evince curiosity along such lines before puberty is traditionally considered wicked, and persistent curiosity may be a sign of degeneracy. There is the matter of auto-eroticism, or self-abuse, for which parents and teachers refer small patients. From infancy on a child may drift into this practice, discovering its comforting sensations like thumb-sucking as an inducer of sleep, or stumbling on the mechanism as part of exploratory investigations conducted alone or with the help of other children. The medical advice in dealing with this matter has been far from wise and helpful. In common with parents and teachers, physicians too have been horrified, tying the child's hands, threatening to cut him with a knife, placing him in steel frames to sleep, and telling the child and his grown-up guardians that the practice is causing his body to deteriorate and will in all probability result in insanity or feeblemindedness. There is absolutely no truth in these fears. Auto-eroticism is seen openly practiced by individuals unbalanced enough to require institutional care. The same individuals are also seen spitting on the floor, and taking off their clothes and eating with their fingers. The latter behavior is recognized as a symptom of the unbalance, not a cause. In exactly the same way auto-eroticism is not a cause but a symptom, and as such it must be treated with intelligence. Do not worry about it and scold and watch the child every minute. See that he has plenty of chance to play and become thoroughly tired, and find interests more absorbing. The practice may not disappear at once or entirely, but it will greatly diminish. There is no physiologic danger connected with the habit. Havelock Ellis, a great English authority on the instinctive life, states that 98 per cent of normal adults go through an auto-erotic period from 12 to 20 years of age. Parents should take interest in the child's play. When he is small he should have toys that are suited to his level of enjoyment; more important yet, it should be remembered that it is a poor policy for any child to play alone even with the finest equipped playroom and yard with sand pile and swings. Adam grew tired of even the Garden of Eden. In like manner a child wants somebody to talk to, to argue with, to vie with in competition, to enter into his imaginative fancies. What if the neighbors' children teach him bad words and impudence, or give him contagious diseases, he cannot be desensitized to these things too early. Better chickenpox and blasphemy than a child established in habits of selfishness inevitably associated with being solitary in all his ways.

COMMENT

I have mentioned somewhat in detail a few principles that the physician should keep in mind in considering the mental health of every small patient with whom he comes in contact. Their embodiment in practice might be considered the equivalent of a psychiatrically intelligent approach to pediatrics. A well known pediatrician writing Dr. Crothers says, "The psychiatrists have simply discovered a lot of things which doctors in general have known for many years." I have no doubt that the gentleman making this statement thoroughly believes this to be true, and yet the record of floundering in the treatment of nerves which the medical profession has established for itself over a long period of years is nothing to boast of. If even a preschool child either in dispensary or in private practice is asked what he and his mother are coming for, the diagnoses and medical discussions of every physician he has visited since he was old enough to understand words can be obtained instanter. Histories of patients are complacently taken from their parents, and theories of heredity and diagnostic fears are discussed in the presence of children, and then physicians wonder why these little folk whine over food, are afraid to run and play, and must sleep in mother's room. I have heard a professor of pediatrics give an hour's clinic over a 10-year-old patient with congenital heart disease and not understand why the child developed an invalidism a year later that was out of all proportion to his organic necessities. I have known a professor of ophthalmology to tell the mother of a 12-year-old girl with congenital glaucoma that she would become totally blind at 18. The child was sitting beside the mother and heard every word he said, developing then and there the roots of a chronic and persistent insomnia that for years handicapped every activity of her life. All over the country are physicians buoying up the parents of defective and retarded children with the prophecy that feeding glandular extracts, removing tonsils and adenoids and doing circumcisions will make these children intellectually normal. If such procedures are necessary they should be carried out, but precious years for special educational training should not be sacrificed to prophecies based on wholly inadequate scientific data. In short, from a behavioristic standpoint, one could write volumes on the topic, "foci of medical infection." Psychiatrically intelligent medicine and pediatrics call for something more than common sense; they call for trained common sense.

How will one go about training psychiatrically intelligent internists, pediatricians, obstetricians, gynecologists and orthopedists? From the behavioristic side of science one must frankly admit that the profession is confronted with a confusing amount of words and theories tending to proclaim some particular field of psychology and psychiatry as the one and only method of human salvation. There is orthodox psychology which claims that a study of intelligence functioning saves one any need for attempting so-called character and personality analysis. Opposed to this is behaviorism which makes environment and training the sole determinant of mental health. And again there is the psychoanalytic school of psychiatry that overemphasizes and overadvertises repression as the black plague of the soul. Is psychometric examination the only method of approaching the personality problem? Is it necessary to scrap the facts of heredity and eugenics in order to do justice to environment and training as behavior determinants? Shall society sit by and await with patience the day when biochemistry teaches it how to "change the personality with glands?"

As much can be suffered from training without common sense as from common sense devoid of training. It seems to me that the safest guide in approaching the mental health of childhood is a good general background in the field of medicine which includes training and a practical working knowledge of the integrated mental and physical functioning of a human being. The time is coming when every medical school will follow the example of the larger medical institutions of learning and place psychobiology and psychiatry on exactly the same basis in the curriculum as physiology and internal medicine. Rotating hospital services will include periods of resident training on psychopathic wards and in psychiatric dispensaries. The physician with this background of medical school and hospital training will then be equipped not only to treat the health of the child as a whole with a feeling of reasonable security, but also to utilize and correlate a wealth of helpful contributions from the broad field of education, psychology, sociology and psychiatry.

No one group of society has an exclusive claim on the mental health of childhood. It should be the active concern and intelligent interest of every constructive force in our social organization that comes in contact with the welfare of children.

Johns Hopkins Hospital.

PEDIATRICS AND CHILD PSYCHOLOGY *

JOHN E. ANDERSON, Ph.D.
Director, Institute of Child Welfare, University of Minnesota
MINNEAPOLIS

In an age in which the word psychology is so widely used by so many different people in such a variety of ways, one approaches the discussion of the relation between psychology and pediatrics with some fear and trembling. This is in part due to a feeling that, when the discussion is completed, psychology may seem to be a much more prosaic endeavor than most people believe, and to hold out somewhat less hope of meeting all our unsolved problems of human relations, at least within the next generation.

To many, psychology is a word to be glibly rolled off the tongue, whenever an inexplicable fact of human action occurs or a quick and easy explanation is sought. To those who are earnestly engaged in the business of trying to formulate valid principles of human behavior and to contribute to our understanding of human nature, psychology is a term which, however hard to define, nevertheless stands for a wide discipline, within which there are many individuals of high ideals who pursue their studies with as keen a comprehension of scientific method, as honest an appreciation of the difficulties of making valid generalizations, and as well trained imaginations as those who are to be found in other of the great scientific disciplines.

---

* Read before the Section on Diseases of Children at the Eighty-First Annual Session of the American Medical Association, Detroit, June 25, 1930.

Unfortunately, these workers, who are slowly but surely building a science, seldom secure the ear of the public and to their regret must see their field constantly misrepresented and exploited by the charlatan and the quack in a manner not unlike that which works to the harm of scientific medicine. Furthermore, all manner of men find their way into psychology just as all manner of men find their way into medicine. Occasionally quite as much harm is done by one within the field who, transcending his scientific principles, runs off into quick and easy and, I fear, popular generalizations, as is done by those outside. But the basic structure of knowledge and technic built up by the effort of many faithful workers, which carries us forward bit by bit to a knowledge and mastery of problems and events which previously seemed quite beyond the reach of human endeavor, must not be forgotten.

At the outset, it is well to distinguish between the quest for knowledge and the application of that knowledge in a practical way to human affairs. This distinction is reflected in the use of the term science and art, the first being concerned with knowing and the second with doing. This distinction is not new to medical men, for the great teachers have consistently pointed out that medicine is an art, built on certain basic sciences, and that medicine becomes ever more scientific as it utilizes more and more the knowledge that is accumulated by sound methods and technics. The great majority of psychologists are university and college instructors who in their laboratories are pursuing the goal of knowledge and who find their material taken over into a variety of practical arts, such as education and industry. The popular idea of a psychologist pictures him as one who is very successful in his own relations with other persons and one who is quite willing to give advice on all occasions to all persons. This is far from the true picture, as the majority of psychologists are no more practitioners than are the majority of physiologists, botanists or zoologists.

It is my purpose in this paper to discuss the relation of pediatrics to child psychology. The occasion arises out of the increasing emphasis being placed on methods of child training and problems of adjustment in this age and the many demands that are made on the physician educator and scientist for information and assistance.

It is quite natural that such a demand should arise as the final capstone of campaigns to improve the health of children. During the last three decades the public has been trained to look to the physician and nurse for information on health. Having been trained to seek the advice of scientifically trained people, the public turns to those who have previously helped them for information and advice on the more complex problems of child rearing.

This shift in emphasis may be a necessary outcome of the progress of today. Because of the overwhelming insistence of physical problems and of disease in the form of specific pain and the constant reminder of death which is present for all of us, medicine arises early as an attempt on the part of society to preserve and maintain life. Since the problems of mental adjustment, although equally serious, are not so immediately insistent, the sciences and disciplines that deal with mental adjustment arise later and assume specific form much later. When children are starving or are critically ill, it avails little to talk about training problems. The first task is the relief of the starvation and illness. When the children are reasonably well fed and in tolerably good physical condition, problems of mental adjustment or training arise.

Psychology as a science appeared relatively late; well after anatomy, physiology, chemistry and physics. Psychiatry, as the branch of medicine which deals with mentally ill and abnormal individuals, arose even later. Psychology is to be looked on as the science which concerns itself with the main trends or general laws which guide and control the behavior of human beings in relationship to their physical environment and to one another. While Dr. Richards will discuss the relationship of psychiatry to pediatrics, it nevertheless may be worth while for me to point out that psychiatry, working as it does in the field of abnormal phenomena, necessarily concerns itself more with the study of individual cases or variations rather than with basic or common trends.

In a sense, every individual in the world is a practical psychologist because he is engaged in the process of adjusting himself, of meeting other people and of reacting to them, and, whether he likes it or not, must formulate principles of conduct and deductions with reference to the conduct of others. The experimental psychologist or scientific psychologist is interested in substituting for the popular psychology on which every one must react a psychology based more definitely on demonstration and verification through the tools of thought which science has developed so admirably in other fields.

In the past, psychology has been largely interested in adults. Within recent years it has become increasingly evident that the adult can be understood only in terms of the processes that have preceded adult life. A somewhat similar development is occurring in medicine, as I understand it. Just as every succeeding year demonstrates the importance of a long time or developmental view of disease as contrasted with a short time or cross-section view, so the more one studies human behavior the more important the developmental approach becomes.

Then what has psychology to offer the pediatrician? The answer to this question is not as easy as it would seem at first glance. If such a science as chemistry or physiology is considered, it becomes clear that much material has been brought together under one heading which has fairly direct bearing on many of the problems which the pediatrician faces. But there is also much in these fields which has little or no bearing.

The contribution of the basic science is composed in part of a general background of terminology, concept and understanding with which problems can be approached, and in part of a matter of specific technic which can be applied in particular situations. In the psychologic field, through the activities of many scientific workers over the years, much material has been accumulated, some of which can be looked on as background and some as specific contributions.

First of all, man exists, in a world of other individuals and is a behaving unit meeting other behaving units of a similar sort. The knowledge of how human beings react should be a part of the knowledge of every one. A child is a growing, active, developing, adjusting person meeting the demands of a complex world. It is only within the last few decades that a serious effort has been made to determine the nature of the child and the manner in which he is brought into adjustment to the world about him. An understanding of the child's native equipment, of the manner in which he learns, of the way in which he thinks, feels and reasons, should be a part of the intellectual possession of every individual who is in any way concerned with children, as parent, physician or teacher. I regret that it is necessary for me to speak in such general terms, but if one looks at a standard textbook in psychology, one finds a book of 400 or 500 pages, embodying the results of hundreds of investigations, which can be mastered only by considerable effort.

If the student of behavior wishes to go back of the elementary textbooks to the more advanced works dealing with particular phases of psychology in detail, he will find literally thousands of books and monographs available. As current sources of material, he will find some twenty scientific periodicals in the United States devoted to psychologic work and as many more published abroad. Out of this great mass of material there is slowly evolving a well integrated and basic mass of psychologic fact.

INTELLIGENCE TESTS

As to the specific contributions which psychology can make to pediatrics, I have time to mention only two in detail. Of these, the first has attracted the greatest amount of public attention and has been the basis of much discussion. I refer to the widely used intelligence tests. Much misunderstanding as to the purposes and significance of intelligence tests has arisen. This has resulted in part from the use of the general term intelligence, to describe what is in fact a measurement of a fairly specific aspect of the whole total of the individual's behavior, and in part from the widespread tendency to interpret test results as placing the child in a permanent category. While it is true that such tests have been exceedingly useful in sorting out defective and retarded individuals and in the development of special technics for the education and training of both retarded and gifted children, nevertheless there is nothing inherent in the intelligence test itself which sharply defines or characterizes the whole adjustment of the individual to his life situation.

The intelligence test has predictive value within certain limits and for certain types of life situations. Narrowly and carefully interpreted, the results are of great significance and practical use. When the results of such tests are looked on as closing an individual case rather than as a basis on which wise guidance, treatment and control can be developed, they defeat their own purposes. While the overpopularization of tests has been somewhat harmful, in the main their widespread use has contributed to the welfare of all children. New principles of education have been developed around individual differences. Society has moved from a lockstep system in which all children were treated much alike to a system in which endeavor is made to accommodate the kinds and type of instruction to the capability of the individual child.

For the pediatrician the intelligence test represents a fairly simple measurement made by a technically trained person, which will enable the physician to gain new insight into difficult cases and make possible better recommendations for the care of the child. If he expects the test to solve all the child's problems he will be disappointed, just as would be the case if he took one of his other laboratory technics built up for a special purpose and tried to solve all his problems of physical disease with it. Some acquaintance and understanding of the use of intelligence tests will also give him an insight into the wide variation that exists among children, and the necessity of approaching each child as an individual.

THE TRAINING OF YOUNG CHILDREN

The second specific contribution which the psychologist can make to the pediatrician is likely to be found in the recent attack of the psychologist on the problem of the development and training of young children. Within the past five years a number of institutes for the study of children have been established, usually with schools for young children as an integral part. In these institutes in which physician, psychologist, sociologist and educator cooperate in a wide variety of researches, much material is being accumulated that is of direct and practical significance for the problems which the pediatrician meets daily in his practice. Space does not permit my going into detail. I might mention, however, the Minnesota studies on sleep and the Toronto studies on basic habits. It is too early as yet to predict the extent of the contribution which will be made, but it is clear that any group of scientists attacking the complex problems of the young child from observation, contact and study, rather than from the armchair or an exclusively adult point of view, is of necessity bound to develop a sympathetic attitude toward the work and possibilities of pediatrics and to make contributions to the work of all those concerned with children.

In the past, entirely too much of our material on child life has been projected back from our knowledge of the adult rather than built up progressively from the actual observation and study of children. Much harm is done by the assumption that children are but adults in miniature, and that any one who knows adults necessarily knows children.

If the psychologist offers the pediatrician his material on children, he has, I think, a right to expect something in retu[illegible] That something which he expects is a sympathetic [illegible] basic principles of child life and of the modification of child behavior. Some pediatricians show an excellent knowledge built on the basis of their practical experience with hundreds of children. Others seem to be almost completely ignorant of the fact that they are handling a child rather than a disease or a particular physical condition.

HOW TO GAIN KNOWLEDGE OF CHILD PSYCHOLOGY

May I add a word about the specific procedures through which the physician and pediatrician may gain some knowledge of child psychology. First of all it seems to me that every educated person should have some contact or acquaintance with the elementary facts of human behavior as presented in the ordinary or beginning textbooks of psychology. Granted some acquaintance and general background, there should be the contact with normal or typical children which seems to be so worth while and valuable in gaining a point of view with reference to children. The establishment of well baby clinics which in many medical schools constitute a part of the training of the pediatrician constitutes a decidedly worth-while step in this direction, for here the student sees not the ill children of the wards but those with minor difficulties arising in the ordinary home environments. If to these well baby clinics there could be added limited opportunities for the observation of children in groups or at play, such as are furnished by our modern schools, particularly those for young children, I think much would be gained. It is one thing to see a child for five or ten minutes in a forced or strained situation and another thing to see children who are under no pressure or strain at their activities for a considerable period. Particularly valuable in the training of the young man entering the field would be the observation for a short period of a highly skilled teacher of young children at her work.

As the pediatrician practices, he is apt to become more and more inclined to base his generalizations and practical recommendations on briefer and briefer observations and contacts with children. This is a natural tendency, in view of the growing demands that are made on one's time. But it is a tendency that can be counteracted with some profit by taking every opportunity to see children at their ordinary life in play, school and home, both as individuals and as groups. Occasional visits to schools, trips to playgrounds, visits with families, all are of value in building up a sound view of child life. After all is said and done, what Dr. Crothers calls a wise and tolerant curiosity about mental processes and an attitude of respect toward the emotional and intellectual difficulties of the child cannot be acquired without manifold contacts with children in all aspects of their lives.

IMPORTANCE OF THE PEDIATRICIAN

Finally, I wish to point out the important position held by the pediatrician in relation to the children under his care. He sees them from time to time throughout the period of their most rapid growth; he is consulted by the parents both during emergencies and when emergencies do not exist. If he is interested in the whole adjustment of the child, he can do much in his incidental contacts with the children and with the family to further their well being with respect not only to their physical health but also to their mental health.

The manner in which the individual physician will respond to this opportunity depends to a large degree on his personal characteristics, training and interests. As the physician himself practices, he is modifying his own nervous system and is building the particular modes of responses which will later become characteristics of his whole approach. If he rushes in and rushes out paying attention only to the physical needs of the child he will soon find himself by the very nature of his work restricted to a narrow point of view. On the other hand, if he takes a sympathetic and wise interest in all phases of child life he will find not only an increased interest in all phases of his work but also a return flow from his general interest in children and their adjustment problems back to his efforts and procedures for the physical care of children. He will then become a sane and wise counselor, well equipped to give the children under his care a good start on the road to successful and happy living.

SUMMARY

I have pointed out that:

1. Despite the popular loose use of the word psychology, there is a considerable body of able scientific investigators who are gradually building up a substantial body of knowledge about human behavior.
2. As the physical health of children is improved, questions of mental health, learning and adjustment arise and more and more demand is made on the scientist and physician for information and guidance.
3. The contribution of psychology to pediatrics is both general and special. The first consists of a background of terminology, concept and understanding and the second of technic such as the intelligence test, and such specific results as may be expected from the coordinated attacks of physician, psychologist, sociologist and educator on the life of the young child, shown in the recently developed institutes for the study of children.
4. The psychologist may expect from the pediatrician in the future a sympathetic understanding of the basic principles of child life and the modes of modifying child behavior.
5. Through contact with children in school, on the playground, at home, at work and at play, *en masse* as well as individually, the forward looking pediatrician can supplement his contacts with children as patients in such a way as to become an intelligent and wise counselor on all aspects of child life.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. RICHARDS AND ANDERSON

Dr. A. H. Parmelee, Chicago: It is hard for me to understand how a pediatrician can escape a sense of responsibility in regard to the mental hygiene of his patients. Certainly not a day goes by but that some patient comes to me in whose case there are points which need some sort of psychologic interpretation. I can see, in the forces that are sending physicians into a study of this phase of child health, a definite similarity to those which sent physicians into an intensive study of infant feeding. They are being forced into it by public demand whether they wish it or not. Twenty or thirty years ago the public began to be flooded with literature, bulletins and talks about proper, well balanced diets for infants and children. Certain men began to be more or less expert in the feeding of infants and young children, but the majority of physicians found that their patients often knew more about the subject of infant feeding than they did: they asked a lot of questions which many physicians could not answer. Consequently, infant welfare societies and other public health centers for conveying feeding information were established because the public demanded it. A similar situation arises today with the great amount of interest that is being shown by the public in regard to mental health. Interest of parents in their own mental health has inspired them to take measures to protect their children from the handicaps they themselves have suffered through ignorance of mental hygiene on the part of parents, teachers and physicians. The psychiatrically minded pediatrician need not be a psychiatrist. His knowledge can only be general but should be comprehensive enough to enable him to handle the usual case and know when to send a child to a real psychiatrist. I am afraid that sometimes a child is branded as a "problem child" by being inadvisedly referred to a psychiatrist when the pediatrician should have been able to handle the case in a more simple way; just as the child who is a little bit slow in school is branded among his schoolmates by being put inadvisedly into the so-called opportunity class.

Harry J. Baker, Ph.D., Detroit: The White House Conference on Child Health Protection has a subcommittee dealing with the problem of what the schools shall do with behavior problems. The committee consists of a psychiatrist, a pediatrician, a school principal, and myself as a school psychologist. We are trying to get at the problem of what to do with the children. We have discovered in the past few years that if we study the intelligence distribution of children who are known to be behavior problems, if we can speak of them as a general class, we find that as a group they are somewhat dull or slow children, not feebleminded but slow. We have a suspicion that our school organization has not handled the psychology of slow children properly. It is one of the important challenges of education to build a curriculum suited to the mental capacities of slow children so they should at least be happy and grow up into what is considered the best that can be offered from the standpoint of school mental hygiene. From the standpoint of the practitioner and of the child, it seems necessary many times to exercise great patience to keep the child in its present school environment. From the standpoint of the teacher with a crowded room and a school administrator with many complaints coming in of malbehavior of children, it may seem desirable to segregate these children. School administrators are quite embarrassed between two rival forces in knowing what to do with this problem alone. I believe that teachers as a whole are quite sincere in wishing to do something with problem children. Many lack technical training. One of the problems of the conference is to decide what sort of program of training a teacher should have in order to understand problem cases better. I believe that at least 3 or possibly 5 per cent of all children offer serious adjustment problems in school. Part of the survey made recently shows that less than 4 per cent of the large cities of the country are really doing anything to handle this problem.

Dr. Paul J. Zentay, St. Louis: The beginning of this new era has been described as a revolution. Such a revolution is actually in process whether physicians want to accept it or not. And it is taking place in the whole field of medicine and in pediatrics in particular. It is well known that through many phases of development a stage in medical science has been reached where old conceptions must be rewritten in terms of biology and pathology of the human person. The general practitioner or the pediatrician of today has to deal with the whole human individual and has to study the problem on that basis. Dr. Gesell recently stated that pediatrics of the future has to be rewritten in terms of behavior. I think that, after listening to the symposium this morning, all feel that there is a great deal of truth in this statement. The symposium makes it evident that the problems are primarily of genetics and development. Pediatrics seems to be the only branch of medical science that is primarily interested in genetics and development. It is trying to follow up the child from the first moment of life to adulthood. This has necessarily to include studying the genetics and development of the psychic side of the child. Pediatricians are particularly in a position to promote the mental hygiene of childhood. The outstanding problems in this field have been pointed out in the symposium. The important need, in my opinion, is a more intensive research in studying child life. Physicians have to get more complete biographies that follow the child from the first moment of life until adulthood. Through them they will be able to understand more thoroughly all reactions and integrations of the child. The speakers and also the discussers have emphasized the need of more intensive training in this field. This seems to be unavoidable for pediatricians of the future. With better training, pediatricians will be in a position to apply principles of mental hygiene in infancy and preschool age, when most needed and when results are more promising, that being the stage of development when mostly pediatricians can reach the mother and the child.

Dr. Harry Stack Sullivan, Towson, Md.: From birth onward, the human individual is a social creature. The factors of principal import in his environment are social—are interpersonal relations. When the pediatrician or the psychiatrist interested in children considers a particular child, he must realize that he is dealing with the nexus of a social situation. The ultimate problems confronting them are not to be solved by anything they can do to the child as a separate entity or to the important other people considered as separate entities. In many cases the problem concerning this nexus is one that can be dissipated by the use of "enlightened common sense." Enlightened common sense consists in part of a body of superstitions, some of which are conspicuous ingredients of so-called mental hygiene. Dr. Anderson is one of the workers who are accumulating facts with which the superstitions now included in common sense as applied to child guidance and correction can finally be replaced. One of the greatest steps in mental hygiene is the institution of regular feeding and sleeping habits in infancy. Considered from the standpoint of personality genesis and evolution, the principal import of infancy is embodied in the learning by the individual of the boundaries of reality and of himself. To the extent that he learns that there are rigid uniformities and consistencies in the universe, to that extent he has gone a long way in an exceedingly new fashion—that is the personality implication of the inculcation of regularity in sleeping and feeding. Speaking as one from outside this section, I would wish to counsel its members to a certain caution in adopting verbal formulas from various disciplines. The formula often omits essential factors used effectively by the specialist without his awareness of their importance. His experience is frequently reflected but poorly in the utterances of any specialist, even those of a synthetic chemist There is a great deal that can be done by any medical man when he is inspired by the correct view of the individual. The creation of child study institutes and the accumulation of scientific material should be encouraged by every means. The person, infant or adult, is not a concrete unitary entity running around loose, but instead is invariably the nexus of a complicated fabric, and not carriers merely of tissues and organs.

Dr. Bronson Crothers, Boston: Psychiatry and psychology are far from being fads. They are absolutely inevitable parts of the intelligent general practice of pediatrics. The human contacts the pediatrician forms give him enormous advantages over the specialist who is called in after trouble begins. He knows, or ought to know, the character of the parents, how they have succeeded with their other children. He ought to know, at least, in general, the effect which the educational program devised for that particular child has upon him. It is perfectly evident that there are different kinds of education in private schools. One school may develop a peculiar type with great regularity. That is a thing which must be taken into consideration to decide whether or not anything shall be done about it. Another thing is that the present technic of elaborate psychiatric and psychologic clinics is adapted primarily to the discovery of new facts. It can hardly cover the entire ground. Public demand is such that children are going to be taken care of somehow. There is a strong effort being made to jump over the pediatrician largely because the pediatrician has not been sensitized to the situation. Dr. Richards speaks of a desirable situation occurring by which the pediatrician should be psychiatrically intelligent. I think that one of the serious dangers is that, if pediatricians do not become psychiatrically intelligent and educationally sensitive, the work of handling the child will be taken up by some one not pediatrically intelligent. I think that this would be a great pity. I think we have a fragile hold on a favorable position. If we can stay in, we are in a position to take advantage of advances quite definitely. Furthermore, every one will recognize that the handling of chronic disability is primarily a medical responsibility. I think no one would decry for a moment that the slightly handicapped child can be enormously mishandled from an emotional standpoint. So, an extraordinarily simple position in handling chronic disease is taken and if account of the emotional factors that must be set up by disability is taken, we shall go some distance. If habit training is regarded as something more than getting in vitamins and calories, another long step will be taken. After we once get that far, we must be extraordinarily stupid and unseeing if we do not try to grasp what we can from the efficient, elaborate technic of psychiatry and psychology. Psychiatrists and psychologists ought to prepare carefully to educate us. I do not feel that their efforts in this regard are by any means perfect.

Dr. John E. Anderson, Minneapolis: One comment occurs to me in line with what Dr. Sullivan has mentioned. It is to the effect that there are now being established in various universities in the United States organizations for the study of the development of children, which utilize the services of pediatricians, psychologists, sociologists, educators and other scientists in a combined attack on the scientific study of child development and which give promise of making substantial contributions to all phases of our knowledge of children. Much of the difficulty in handling children arises from the fact that adults assume, because of knowledge of how adults act, that they can therefore handle children, and because adults carry back from adult life into the life of the child many principles and facts without making a study of the child at his own level. It seems to me that pediatrics, if it realizes its scientific possibilities, is in the fortunate position of furnishing material for a reworking of much of the field of medicine and behavior, since the pediatricians are the people who see the developing person from birth through to adulthood, and who therefore have an integrated point of view with reference to behavior and development. The stage is past when one can look at a disease or an individual at any particular level and say that at that particular level one knows all about the disease or individual. In the present period the developmental history, the genetic story of the progress of the individual, is important. The child must be studied at his own level. Actual daily contact, observation and experiment, rather than the spinning of theory from armchairs, will contribute the important generalizations of the future.

Dr. Esther Loring Richards, Baltimore: In educating ourselves as physicians, teachers, social workers, psychologists, we have to beware of the great field of diverse opinion in the scientific study of behavior. The physician who has only a little time to read works on this subject is apt to be prejudiced by reading one single article. The field of child study as it is being developed in institutes such as the child Welfare Bureau of Iowa, the Minneapolis research station of Dr. Anderson, and in various other institutions of this country is bringing us invaluable material. On the other hand, I think we have to realize that the formal child guidance clinic as it is being thrust upon us sometimes is a little bit magnificent for our practical needs. In one clinic in this country, I am told, it costs about $500 to make a complete examination of one child. That is a little "steep," I think. I feel we have to realize that we are obliged to choose from many different brands of psychiatric intelligence which come to us, and that the choosing of that is not something that can be done in a hurry or with prejudice. We can make such choice only after a thoughtful consideration and acquaintance with the broad field of behavior study as it develops reliable data on which to base theory.

Clinical Notes, Suggestions and New Instruments

RAYNAUD'S DISEASE OF THE UPPER EXTREMITIES: CURE AFTER THORACIC SYMPATHECTOMY

Anatole Kolodny, M.D., Ph.D., Sioux City, Iowa

When Raynaud first described the disease subsequently named after him, he expressed an opinion that the circulatory disturbance in this disease was due to a vascular spasm. Recent microscopic study of the capillaries of the terminal phalanges of the involved extremity showed that the original suggestion of Raynaud is correct, and that the anatomic substratum of the disease is a prolonged vascular spasm due to irritation of the vasoconstrictors. Surgical treatment of this disease then suggested itself. It consists in an interruption of the path of the vasoconstrictors and in such a way in an abolition of the competition that the vasodilators have to meet. Deficient knowledge of the anatomy of the sympathetic vasotonic system up to recent years blocked the way of the evolution of surgical treatment of this disease. The periarterial sympathectomy of Leriche failed to effect a cure because of the fact that the sympathetic nerve system has a segmental distribution and that by a periarterial sympathectomy one actually interrupts only a small part of the sympathetic impulse to the extremity.

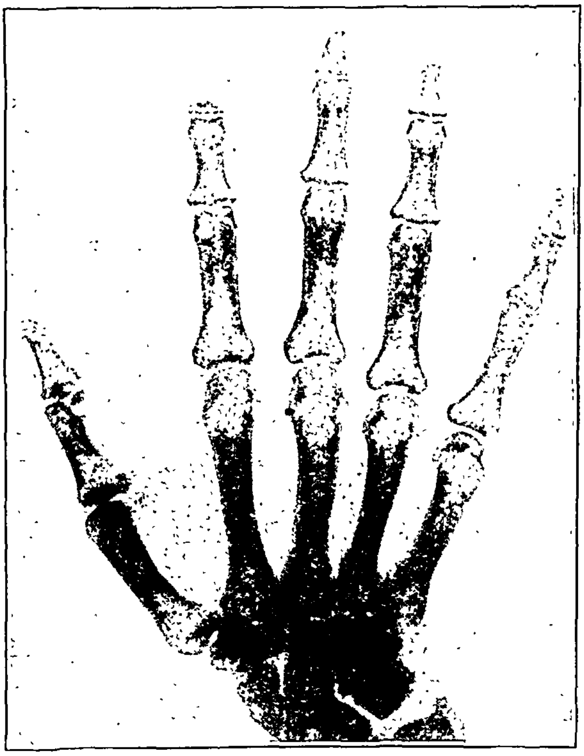

Fig. 1.—Atrophy of distal phalanges of the right hand.

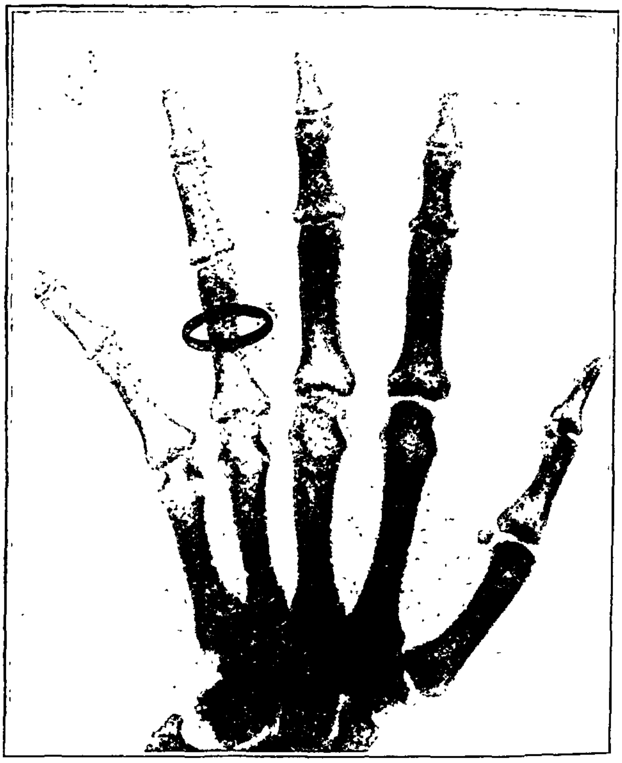

Fig. 2.—Appearance of left hand. Note the bony changes in the terminal phalanx of the little finger.

Raynaud's disease of the lower extremities is cured by a lumbar ganglionectomy. This is a well proved clinical fact. More difficult was progress in treating Raynaud's disease of the upper extremities. Cervical ganglionectomy was found to be wanting in effecting a cure. Only after Kuntz[1] demonstrated that a large number of the sympathetic fibers supplying the upper extremities pass through the second thoracic ganglion was it clearly understood why a cervical ganglionectomy failed therapeutically. In 1929, Adson put to test Kuntz's information. He suggested the removal of the second thoracic ganglion along with the stellate ganglion. The technic of this operation is described by Adson. In May, 1929, Adson[2] reported two cases in which he operated by this method, with good results.

Obviously, such cases are not frequent, and it might be of interest to put on record a patient with Raynaud's disease of the upper extremities on whom I operated in September, 1929.

REPORT OF CASE

A Bohemian woman, aged 30, had been noticing for many years that her fingers became pale and numb on exposure to cold; on a change to warm weather her fingers became red and swollen and tingled. At first these sensations were not so severe and would occur only in the winter, but in 1927 they began to come on at the slightest change of temperature the year around. All of the fingers of both hands would become numb; they tingled and pained. She had no relief between the attacks of pain. Soon black sore spots appeared beneath the nails at the tips of the fingers. To relieve the pain somewhat, she held her hands wrapped in a blanket, when the fingers would become quite cyanotic and perspire freely.

[2] Adson, A. W., and Brown, G. E.: Surg. Gynec. Obst. **48**: 577-602 (May) 1929.

The patient was apparently in normal health, with the exception of somewhat stiff fingers covered with puffed bluish skin. Large drops of perspiration were seen over the fingers, especially on the palmer side. There was atrophy of the terminal phalanges of most of the fingers. The terminal phalanges of the right index finger and of the left little finger had disappeared almost entirely. The blood pressure was 132 systolic and 84 diastolic. The roentgenogram showed atrophy of the distal phalanges (fig. 1).

September 20, I operated under ether anesthesia. The stellate and the second thoracic sympathetic ganglion on the left side were removed. Examination in the afternoon showed the left hand to be pink, warm and dry, while the right hand was cold, moist and cyanotic. A slight Horner's syndrome was present on the left side. On the third day after operation the patient developed a pneumonia limited to the left lower lobe. The patient remained at the hospital six weeks. During the entire time of the patient's stay in the hospital the marked improvement in the circulation of the left hand persisted, and the patient was entirely free from any of the former symptoms in the left hand, while the clinical picture of the right hand has not changed. A letter from the referring physician, Dr. Keough of Dubuque, Iowa, of May 19, 1930, reads, "Your operation helped her a great deal on the left side. The result was wonderful."

Frances Building.

WHIRLPOOL BATHS AND POSTERIOR SPLINTING TO OVERCOME CONTRACTURES IN BURNS

J. W. Hilbert, M.D., South Bend, Ind.

Contractures occurring secondary to burned areas about a joint are always problems of considerable magnitude, especially when the disability and compensation factors are taken into consideration. Many methods have, in the past, been used, such as open method with extension and weights, paraffin method and sand bagging, all of which have caused considerable pain to the patient and many of which had finally to be discontinued either because of the discomfort or because they were not practical over a long period of time.

I report this case merely because, as far as I can discover, the method used is unique, is easily carried out and gives excellent results.

July 8, 1930, a white man, aged 24, sustained extensive second and third degree burns to both extremities from the ankles to the middle third of the thighs. The whole circumference of both limbs was involved. A thick application of ointment dressing was applied and the patient removed to the hospital. Within twenty-four hours the patient presented a toxic picture with chills, fever and rapid pulse; he became delirious; the urine showed albumin, much pus, granular casts and blood. The routine procedure of relieving the kidneys was followed with normal response, but by the fifth day sloughing of the burned areas and purulent secretions became very extensive. Because of the pain associated with the dressing and cleaning of the parts, the patient's extremities were subjected to whirlpool baths, at a temperature beginning at 100 F. and increasing to 110, for ten minutes. This not only took away all secretions and the major portion of the sloughs but also affected a stimulating massage. On the seventh day the first evidences of contractures became manifest and within twenty-four hours there was right angle flexion of the limbs at the knees. Two light weight but strong veneered boards were designed so as to extend from the patient's heels to just below his buttocks. These were tapered from 2½ inches at the distal end to 8 inches at the proximal extremity. After padding with cotton and covering with gauze the splints were placed, one posterior to each limb, and 2 inch gauze ties were used as an anchorage at the ankle and at the middle third of the thigh. By this method the weight of the limb, after twenty-four hours, overcame without pain to the patient almost all of the contracture at the knees, so that the 8 inch distance from the splint to the popliteal space on application of the splint was reduced to 3 inches in one day's time. In another twelve hours the legs were fully extended and the splints were removed. After three days there again appeared some flexion, but this was readily overcome by reapplication of the splints for a period of another twenty-four hours. Whirlpool baths followed by water cooled ultraviolet irradiations were continued daily to July 24, at which time this procedure was done every second day until August 8. After six weeks' time the patient has but a few denuded areas on each leg, which are rapidly filling in with healthy epithelium. He walks normally, without pain; he can flex and extend both limbs normally and will have no permanent impairment.

Council on Pharmacy and Chemistry

REPORTS OF THE COUNCIL

The Council has authorized publication of the following report.
W. A. Puckner, Secretary.

INCREASED POTENCY OF VIOSTEROL PREPARATIONS

The Council accepted viosterol in oil 100 D and cod liver oil with viosterol 5 D and the brands made under license from the Wisconsin Alumni Research Foundation by the following firms: Abbott Laboratories, Mead Johnson & Co., Parke, Davis & Co., and E. R. Squibb & Sons.

The Wisconsin Alumni Research Foundation informed the Council that the accumulated clinical experience with viosterol has shown that better results in the treatment of rickets are secured when a dosage of vitamin D is used larger than that originally recommended. The Foundation in addition points out that the maximum limits of safety as to the amount of vitamin D that can be used has now been more definitely determined than was the case when preparations of viosterol were first put on the market. Instead of increasing the dosage of the present products, the Foundation and its licensees determined to increase the potency of the preparations used. It was decided to increase the potency of viosterol in oil so that instead of having 100 times the vitamin D potency of a standard cod liver oil as determined on rats by the Steenbock line test, it shall have 250 times that potency, and, provided the Council on Pharmacy and Chemistry should agree, to increase the potency of cod liver oil with viosterol so that instead of having 5 times the vitamin D potency of a standard cod liver oil as determined on rats by the Steenbock line test, it shall have 10 times that potency. The Foundation has supplied each of the manufacturers operating under its license with a preparation of viosterol in oil 250 D (Steenbock standard), to be used as a control in the standardization of their respective products. The Foundation announced that these products of increased potency will be put on the market beginning with October first.

The Council on Pharmacy and Chemistry has accepted the changes of potency determined on by the Wisconsin Alumni Research Foundation and has changed the name of viosterol in oil 100 D to viosterol in oil 250 D and the name of cod liver oil with viosterol 5 D to cod liver oil with viosterol 10 D. It has continued the acceptance of the viosterol preparations already accepted, under the new names, viz.: Viosterol in Oil 250 D-Abbott, Abbott's Cod Liver Oil with Viosterol 10 D (Abbott Laboratories); Mead's Viosterol in Oil 250 D, Mead's 10 D Cod Liver Oil with Viosterol (Mead Johnson & Co.); Parke, Davis & Co.'s Viosterol in Oil 250 D, Parke, Davis & Co.'s Cod Liver Oil with Viosterol 10 D (Parke, Davis & Co.); Viosterol in Oil 250 D-Squibb, Squibb's Cod Liver Oil with Viosterol 10 D, and Squibb's Cod Liver Oil with Viosterol 10 D, Mint-Flavored (E. R. Squibb & Sons).

Characteristics Depend on Genes.—All types of characteristics, all manifestations of life, of whatever sort, are alterable by altering genes. . . . Structural characteristics, internal and external, colors, shapes, sizes, chemical properties, physiological functions, senses, behavior—all have been shown to be changed by changing genes.—Jennings, H. S.: The Biological Basis of Human Nature, New York, W. W. Norton & Co., Inc.

SATURDAY, OCTOBER 4, 1930

HEMOCHROMATOSIS

Hemochromatosis is a rare but readily recognized disease characterized clinically by bronzing of the skin, by ascites and other symptoms of cirrhosis of the liver, and by diabetes mellitus. Anatomically it is characterized by the widespread deposition of pigment in the tissues and organs of the body including the skin, to which the visible bronzing is due; by continuous destruction of liver cells and their replacement by connective tissue, to which the manifestations of cirrhosis are due; and by destruction of acinous and islet cells of the pancreas and their replacement by connective tissue, to which the symptoms of diabetes are due. The more exact modern knowledge of the condition dates from the classic presentation of the subject by von Recklinghausen, who in 1889 gave a thorough description of the disease and demonstrated the presence in the tissues of two kinds of pigment. One of these, which is iron-free and which he named hemofuscin, is widely distributed in the connective tissues and smooth muscle, where it usually occurs alone, and in the epithelial cells of various glandular organs, where it is usually associated with the second pigment, which contains iron and has been known as hemosiderin since the time of Virchow. Of the various morphologic changes that occur in hemochromatosis, deposition of pigment is the fundamental one. The other alterations that produce the dominating clinical symptoms are secondary. Characteristic of the disease and necessary for the proof that a given condition is hemochromatosis is the presence of the two pigments. Von Recklinghausen himself derived the deposited hemofuscin from the hemoglobin of the blood, but many of his contemporary pathologists did not consider such an origin well established.

Since the time of von Recklinghausen, nothing essentially new has been added to knowledge of the disease and no new conception of its nature was offered until the work of Mallory[1] of Boston. Ten cases of the disease that came to necropsy at the Boston City Hospital within the course of a single year furnished an unusual material for the study of the pathologic histology of the disease. Also available for study were nine other cases that had been examined post mortem either before or after the series of ten cases. Study of the clinical records of this group of cases brought to light two factors that seemed to have a bearing on the causation of hemochromatosis; namely, excessive indulgence in alcohol or exposure to copper. By the addition of copper acetate to the food of rabbits, in daily doses of 200 mg. over a long period, Mallory, Parker and Nye[2] were able to cause a pigmentary cirrhosis of the liver which, in the presence of both hemofuscin and hemosiderin, in the necrosis of pigment laden cells, and in the connective tissue replacement of the destroyed cells, they held to be identical with the cirrhosis of human hemochromatosis. From his clinical, pathologic and experimental studies Mallory concluded that chronic copper poisoning is the important etiologic factor in hemochromatosis. He believes that hemofuscin is formed from the hemoglobin of the blood, the exact nature of the transformation being as yet unclear. Overloading of the cells of the liver and pancreas with pigment leads to their necrosis and to their replacement by connective tissues. The destruction of liver cells is associated with regeneration of parenchymatous cells, in which the process of pigmentation, necrosis and replacement is again repeated. In the course of time, the process being a slow and protracted one, iron is united to the hemofuscin, the pigment that gives the iron reactions of hemosiderin being thus formed. The development of the complete and typical symptom complex of hemochromatosis takes from fifteen to twenty-five or more years.

The manner in which chronic poisoning with copper causes hemochromatosis cannot be considered fully understood, and the mechanism of the action of the metal does not appear to be a direct and simple one. It is known that in larger doses copper salts cause hemolysis and hemoglobinuria. It is probable that in smaller doses they also cause destruction of erythrocytes, but why the hematogenous pigment that results from the prolonged slight destruction of red blood corpuscles should be distributed so widely as it is or should be retained in the tissues so tenaciously instead of being excreted or changed to bilirubin is not explained. In the case of the human disease, the implication of copper as the etiologic agent is conjectural and is based on a history of overindulgence in alcohol or exposure to copper. Alcohol, usually held responsible for the nonpigmentary form of interlobular cirrhosis, is blamed because the illicit liquors made under the eighteenth constitutional amendment frequently contain copper. Mallory found as much as 185 mg. per liter in one sample of whisky.

[1] Mallory, F. B.: The Relation of Chronic Poisoning with Copper to Hemochromatosis, Am. J. Path. **1**: 117 (Jan.) 1925; Hemochromatosis and Chronic Poisoning with Copper: Tenth Mellon Lecture, Arch. Int. Med. **37**: 336 (March) 1926.

[2] Mallory, F. B.; Parker, Frederic, Jr., and Nye, R. N.: Experimental Pigment Cirrhosis Due to Copper and Its Relation to Hemochromatosis, J. M. Res. **42**: 461 (Oct.) 1921.

In five of the pigmented cirrhotic livers examined quantitatively for copper by Mallory, the copper content varied from 1.5 to 19.1 mg. per kilogram of liver. The copper content of four control livers varied from 0.77 to 20.4 mg. per kilogram, the largest amount being found in the liver of so-called alcoholic cirrhosis.

In the case of the experimental disease, the mode of action of copper is also not completely established. Flinn and Von Glahn [3] of New York were unable, by the long continued administration of copper to rabbits and other laboratory animals, to cause the characteristic pigmentation and cirrhosis of the liver of hemochromatosis. Oshima and Siebert,[4] stimulated by three cases that were examined post mortem in Aschoff's institute in Freiburg, have more recently repeated the feeding experiments of Mallory. Copper acetate in a dosage of 200 mg. daily was administered to rabbits by stomach tube over a period of from 61 to 249 days. Marked pigmentation of the liver resulted and the copper content of the liver varied from 52 to 170 mg. per kilogram of liver, as compared with an average of 6 mg. per kilogram in control animals, but the necrosis of liver cells and the increase in connective tissue of the liver described by Mallory were absent. Furthermore, the iron-free pigment in the liver cells was soluble in alkalis and not stained by fuchsin. Despite their somewhat discordant results, Oshima and Siebert, who had been able to examine Mallory's microscopic preparations, were convinced that the latter had actually caused the development of hemochromatosis experimentally. They believe, however, that some unknown factor must act with copper to cause the pigmentary cirrhosis of hemochromatosis.

In his report of the three human cases, Siebert [5] calls attention again to the marked pigmentation of the synovial membranes of the joints noted by von Recklinghausen, and to pigmentation of the epithelial cells of the hypophysis, not sufficiently emphasized in some previous reports. The gallbladder of each of the patients contained pigment calculi with a high copper content. The patients came from villages devoted to the wine producing industry, in which copper salts are widely used. The incidence of hemochromatosis is higher in this district than in other parts of Germany. The livers of these patients are included in a series of sixteen livers from hemochromatosis examined for copper by Oshima and Schönheimer.[6] The copper content varied from 9.86 to 19.33 mg. per kilogram, as compared with from 1.09 to 3.9 mg. in seventeen normal livers.

While the exact way in which long continued intoxication by small amounts of copper causes hemochromatosis has not been clearly shown, a relationship of cause and effect as between copper and hemochromatosis appears probable. Although hemochromatosis in its fully developed and easily recognized form is a rare disease, the detection by Mallory of hemofuscin and hemosiderin in the liver, pancreas, kidneys and heart muscle of 11.6 per cent of all adults, a total of 463, coming to necropsy at the Boston City Hospital in the course of two and one-half years suggests that milder and incompletely developed forms of the disease may be more frequent than is generally supposed. If the prohibition experiment has led to a decrease of alcoholic cirrhosis, as some have claimed, the continued use of illicit liquors containing copper may lead to a replacement in medical statistics of nonpigmentary interlobular cirrhosis of the liver by the pigmentary cirrhosis of hemochromatosis.

HYPERVITAMINOSIS WITH VITAMIN D

The introduction of irradiated ergosterol in various forms, such as viosterol in oil or cod liver oil supplemented with viosterol, into modern therapy has raised many questions of practical as well as scientific importance. The uncertainty as to the possible toxicity of an agent so uniquely potent as irradiated ergosterol awakened misgivings regarding the desirability of advocating its widespread use. These misgivings prompted the limitation of the recommended dosage within modest bounds. However, it has been repeatedly demonstrated that doses a hundred or even a thousand times those that bring about cures of rickets may be used before disaster ensues. The dreaded specters of hypercalcemia, with its dire effects on the arteries, and of hyperphosphatemia were presently dispelled. The pendulum of dosage had swung so far in the direction of caution that it now seems advisable to increase somewhat the concentration of viosterol in oil and in cod liver oil adopted by the Council on Pharmacy and Chemistry of the American Medical Association for products included in New and Nonofficial Remedies.[1] On page 1021 of this issue the Council reports that the preparations of viosterol in oil formerly having 100 times the vitamin D potency of a standard cod liver oil as determined on rats by the Steenbock line test are increased to 250 times that potency, and that the preparations of cod liver oil with viosterol formerly having 5 times the vitamin D potency of a standard cod liver oil as determined on rats by the Steenbock line test are increased to 10 times that potency.

Another question of moment involves the modus operandi of vitamin D or viosterol, particularly under conditions in which a real hypervitaminosis is encountered. Is absorption of calcium or phosphorus or both augmented in undue degree or do these elements fail to be eliminated to the usual extent, so that a marked positive balance ensues, leading to a surfeit accumulation in the organism? Or, again, are stores like that in the bones mobilized to such an extent by overdosage of vitamin D that calcium and phosphorus circulate in excessive amounts, thereby injuring receptive tissues? There have already been numerous investigations of these questions. Calcium deposits have been described for the kidneys and aorta. It is admitted that hypercalcemia and hyperphosphatemia occur.[2] The latest studies of Watchorn[3] in the Biochemical Laboratory, Cambridge, England, confirm the fact that the deposit of calcium found in certain tissues as the result of large doses of viosterol cannot be accounted for on the grounds of increased absorption and retention. As Watchorn points out, the source of this calcium must be looked for elsewhere, and, unlikely as it appears *a priori* that the action of large doses of a substance that normally aids calcification of the bones should be in the reverse direction, it is difficult to see where the deposited calcium comes from if not from the bones. Although it has been shown that the danger of moderate doses of viosterol is not as great as feared at first and that the dosage may be safely increased in accordance with the action of the Council, the whole question of the action of vitamin D is far from being solved.

ORAL IMMUNIZATION AGAINST PNEUMOCOCCI

Successful immunization against specific infections by oral administration of killed micro-organisms or microbic products would be a major therapeutic advance, since it might free the public mind from its main objections to vaccine therapy. Thus far, laboratory studies have not been encouraging. Apparently most of the suggested oral vaccines are so rapidly destroyed or denatured in the gastro-intestinal tract as to lose completely their antigenicity. Perhaps they take on new antigenicities not specifically protective. Oral immunization, therefore, will presumably be limited to the relatively few vaccines sufficiently resistant to gastro-intestinal denaturization to be absorbed practically unchanged in effective immunizing doses. The most resistant group of micro-organisms thus far studied are apparently the pneumococci. Recently, successful oral vaccines against pneumococci are reported to have been developed by Dr. Victor Ross of the Board of Health Laboratories in New York.

In earlier researches, Ross demonstrated that rats fed with tissues of animals killed by type I pneumococci acquire an increased resistance to intraperitoneal injections with this pneumococcic type[1] and that a similar though less regular type-specific immunity could be conferred by repeated feedings with living cultures.[2] Rats thus immunized would tolerate intraperitoneal injection of from 1,000 to 10,000 minimal lethal doses of type I pneumococci, the acquired type-specific immunity lasting for at least four months.[3] In his hands, heat killed pneumococci afforded little or no oral protection,[2] nor were degraded avirulent pneumococci successful immunizing agents.[4] The development of a successful oral vaccine, therefore, apparently depended on the discovery of a method of devitalizing fully virulent test tube cultures in such a way as not to alter or destroy their initial antigenicity.

Successful methods of homologous devitalization now seem to have been found.[4] Ross reports that pneumococci grown in milk can be devitalized at 60 C. and still function as fairly successful oral vaccines. His most successful devitalizations, however, are desiccated, mechanically disrupted (agate mortar) virulent pneumococci, pneumococci killed by hydrochloric acid, and Berkefeld filtrates from pneumococci dissolved in bile or in sodium glycocholate. Less successful results were obtained with specific polysaccharides isolated from pneumococci.[5]

Ross's most encouraging results are his demonstration of the astonishing rapidity of development of type-specific immunity following such oral vaccinations. "The increased resistance to the virulent pneumococcus is present . . . forty-eighty hours after the material is ingested and can occasionally be detected to a smaller degree at the end of twenty-four hours." In the few clinical trials thus far made, Ross reports that "no apparent discomfort has been found to follow the ingestion . . . of acid killed pneumococci . . . [by patients in doses] much larger than would be required if dosage is calculated on the basis of [relative body] weight." From the theoretical point of view, Ross's "inability to find agglutinins and precipitins in the serums of [orally] immunized animals" and his "uncertainty whether the immunity need . . . be accompanied by an increase in protective value of the serum" is suggestive in its bearing on the newer theories of specific antibody formation.[6]

It is to be hoped that Ross's encouraging researches will not be handicapped by premature clinical or commercial exploitation. It still remains for him to determine whether or not oral vaccines are equally effective for other than type I pneumococci and, if so, whether or not a polyvalent oral vaccine is effective with laboratory animals. Above all, it must be determined whether or not orally acquired systemic immunity to pneumococcic infections is accompanied by an increased specific resistance to pulmonary infection. Too little is known of the relation of systemic resistance to alveolar defense to allow one to dogmatize on this subject. Terrell's[7] generalization that, with local pneumococcic infections, "circulating antibodies appear to have little effect in preventing the spread of the process or determining the outcome of the disease" illustrates the dangers of reasoning from conventional immunologic preconceptions in this disease.

Current Comment

THE CARDIAC OUTPUT IN HEART DISEASE

The output of the heart is of the utmost importance in maintaining the circulation. The amount of blood that passes through the entire body and is available for the metabolism of the tissues depends on the quantity of blood that leaves the heart in each unit of time. It is a well established physiologic fact that the cardiac output may remain constant despite considerable variations in arterial resistance and in the rate of the beat. The primary factor that determines changes in the output is the venous inflow into the heart. As Starling pointed out, the alterations in the vigor of the circulation depend in the first instance on the venous circulation. The greater the volume of the blood that is brought to the heart by the accessory factors of the circulation, the greater will be the output of this organ. Thus the heart is able to vary its output and the work it does according to requirements. A rise in blood pressure within normal limits caused by increased resistance makes no difference to the output except for a few beats. At first the heart fails to drive out its contents adequately, but if the venous inflow is maintained this becomes added to the retained blood to distend the ventricles, which in turn contract more forcibly and overcome the resistance. This phenomenon is sometimes described as the law of the heart. Most of the features that it involves have been ascertained by experiments on animals. In recent years, however, indirect methods have been applied to study the problems involved in man, and of late the conditions existing in persons with heart disease also have been investigated.[8] Experiments at the Peter Bent Brigham Hospital in Boston by Alt, Walker and Smith[8] have included patients with compensated heart disease, chronic myocarditis, and complete heart block who were subjected to moderate, standardized grades of work on the Krogh bicycle ergometer. Measurements were made of the cardiac output, pulse rate and blood pressure during exercise. The response of the cardiac output in the patients with heart disease was not essentially different from the response in the normal person. The Boston clinicians remark that this is consistent with the work of some authors who have found that the output of the heart is a function of the respiratory metabolism. If the heart could not have maintained an adequate circulation with the grade of work used, they add, a cumulating oxygen debt would have ensued and exercise could not have been continued for a long period. Although the response of the cardiac output was quite similar in all of the persons studied, several of the patients with heart disease experienced dyspnea, fatigue and general distress, symptoms that were almost negligible in the normal subject. These adverse subjective reactions were not related to any considerable variation in the measurable cardiac output. Hence Alt, Walker and Smith properly point out that there are yet some unknown factors present in the circulatory mechanism of patients with heart disease. These are manifested by symptoms of dyspnea and fatigue on exertion but are at present unmeasurable by determinations of the cardiac output, stroke volume, vital capacity or respiratory minute ventilation.

BODY FLUID VOLUME IN EPILEPSY

A close association exists between acid-base balance and fluid movement in the body. Edema and dehydration are in large part the resultants of an abnormal disturbance of electrolyte equilibrium. Obviously, therefore, should occasion require, fluid volume can within limits be adjusted by the expedient of manipulating the acid-base balance. It has been indicated[1] that in epilepsy there exists an excess of fluid volume in the supracortical spaces, and one of the modes of treatment that has proved generally efficacious consists of dehydration both through limitation of water and by the ketogenic diet.[2] A somewhat different aspect of the factor of change in body fluid in epilepsy has recently been pointed out by Gamble,[3] who emphasizes the essential automatic defense mechanism of the body during the period of seizure. The acid-base excretion of a patient was observed over the period of seizures, approximately two days, as well as over the four to seven days intervening. It was observed that an irregular excretion of base occurred but with pronounced increases during the attacks, in spite of the fact that the patient was on a diet providing a constant intake of fixed base. Since this periodic accentuated loss was accounted for by sodium rather than by the other bases, it appears that an accompanying loss of body fluid took place, an interpretation supported by the corresponding variation in the volume of urine. Whether or not the loss of base and fluid is caused by the nervous manifestations, the observed correlation will serve as additional evidence in elucidating the details of the pathogenesis of epilepsy.

Association News

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Talks

The American Medical Association broadcasts at 10 a. m. on Monday, Tuesday and Saturday, over Station WBBM (770 kilocycles, or 389.4 meters).

The program for the week is as follows:

October 6. Why Worry?
October 7. Why Worry?
October 11. The Traveling Worrier.

Five minute health talks may be heard over the Columbia Broadcasting System daily except Sundays and holidays, from 12 to 12:05 p. m.

The program for the week is as follows:

October 6. Where Do People Die?
October 7. The Poison Ivy Pest.
October 8. The Sore Throat Danger Signal.
October 9. Everybody's Business.
October 10. Infections Spoil Complexions.
October 11. New Hazards for Old.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest: such as relate to society activities, new hospitals, education, public health, etc.)

ALABAMA

Society News.—During the session of the Northwest District Medical Society, October 3-4, a portrait of Dr. Josiah Clark Nott, founder and first professor of surgery at the University of Alabama Medical School at Mobile, will be unveiled by Mr. James Van Antwerp, the donor. The guest of honor on the clinical program to be given entirely by Mobile graduates will be Dr. John A. Lanford of the University of Louisiana School of Medicine, New Orleans. On Saturday the visitors will be guests at the Alabama-Mississippi football game.

CALIFORNIA

A Million for the Sick Poor.—The largest bequest in the $10,000,000 will of the late Senator James D. Phelan, filed for probate in San Francisco, was $1,000,000 to create the James D. Phelan Foundation to assist without distinction as to nationality, creed or sex in relieving the sick poor of the city and county of San Francisco from disease and suffering and for employing and furnishing nurses to care for them, primarily, in their homes. The trustees are authorized to obtain nurses when necessary, and when nursing service is unnecessary to apply the income to assist the needy sick to personal comfort and quick recovery.

Condemnation of Walnuts.—A survey recently made by the United States Department of Agriculture and the state department of agriculture cooperating with the state department of public health, has revealed that during the season of 1929-1930 a total of 1,594,263 pounds of off-grade walnut meats were condemned. These products consisted of walnut meats that were moldy, rancid or infested with worms, and were placed in sacks and quarantined. The purpose of this inspection of nut cracking establishments, wholesale candy factories and wholesale bakeries as well as cold storage plants, was for the removal of faulty products from the market for the benefit of the public.

Spider Poisoning.—Several fatal cases of poisoning caused by the bite of the so-called "black widow" spider were reported in California this summer. This spider, said to be the only poisonous spider in the country, inhabits the lower half of the United States from coast to coast and obtains the name "black widow" from its custom of eating its mate. The body of the female, which is always responsible for the bites, is often one-half inch in length, brilliantly marked with red or yellow or both, in an hour glass design, and the long shiny black legs may stretch over a spread of as much as 2 inches. In fatal cases death generally occurs in from fourteen to thirty-two hours. A convalescent blood serum, taken from individuals who have recovered from bites of this spider, has been used successfully in the treatment of acute cases.

COLORADO

State Medical Election.—Dr. William A. Kickland, Fort Collins, was installed as president of the Colorado State Medical Society at its annual meeting at Pueblo, September 9-11. Dr. Edward Delehanty, Denver, was made president-elect; Drs. Edgar D. Downing, Woodmen; George M. Noonan, Walsenburg; Isaac L. Gotthelf, Saguache, and Frank W. Lockwood, Fort Morgan, vice presidents, and Drs. Lorenz W. Frank, Denver, and Leo W. Bortree, Colorado Springs, constitutional secretary and treasurer, respectively. Mr. Harvey T. Sethman is the executive secretary of the society.

ILLINOIS

Society News.—Dr. Robert S. Berghoff, Chicago, presented a paper to the McLean County Medical Society, September 9, on "Syphilis of the Heart."——The Quincy Physicians' Club will be addressed, October 6, by Dr. Edmund B. Montgomery on progress in gynecology.——The Peoria Medical Society was addressed, September 16, by Dr. John S. Coulter, Chicago, on "Physical Therapy in General Practice."——Dr. Irving S. Cutter, dean, Northwestern University Medical School, addressed the Rock Island and Moline physicians' clubs in Rock Island, September 16, on "Relation of Cultural Medicine to Medical Practice."——The Alexander County Medical Society was addressed, September 19, at Cairo by Dr. Alexander Brunschwig, Chicago, on "Rare Diseases of the Epiphyses of the Bones of the Extremities."

Chicago

Personal.—Sir James Purves-Stewart of London was guest of honor at a dinner given, September 16, under the auspices of the Chicago Institute of Medicine, the Chicago Society of Internal Medicine, and the Chicago Neurological Society, allied organizations and members of the faculty of Northwestern Medical School.——Dr. Frederick O. Tonney, for many years director of research laboratories of the health department, was recently transferred to the laboratory of the Municipal Contagious Hospital, where he will organize a research department.

IOWA

Society News.—The forty-third annual meeting of the Medical Society of the Missouri Valley will be held in Des Moines, October 15-17, with headquarters at the Fort Des Moines Hotel. The guest speakers will include Drs. Russell M. Wilder, whose subject will be "Glycosurias Other Than Diabetes Mellitus"; Loyal E. Davis, Chicago, "Surgical Treatment of Intracranial Meningiomas"; Willard Bartlett, St. Louis, "A Concept of Thyroidectomy Technic of Today," and Joseph Colt Bloodgood, Baltimore, "Cancer of the Skin and Oral Cavity—A Preventable Disease."——At the Lucas County Medical Society meeting, September 2, motion picture films concerning movements of the alimentary tract in experimental animals and emergency operations, liver-stab wound and bullet wound in the bladder were viewed.——The Scott County Medical Society was addressed, September 2, by Dr. James C. Masson, Rochester, Minn., on "Extra-Uterine Pregnancy."——The Washington County Medical Society was addressed at its annual meeting, September 2, by Dr. George A. Jenkins, Albia, on "The Country Doctor"; Dr. William A. Rohlf, president, state medical society, spoke on various state society matters.——The Upper Des Moines Medical Society, composed of physicians from Clay, Dickinson, Emmet and Palo Alto, held its annual meeting at Spirit Lake, August 14; the following physicians from Rochester, Minn., spoke: Hugh Cabot, on "Relation of the Catheter to So-Called Catheter Cystitis"; Harry M. Conner, "Treatment of Pernicious Anemia"; William H. D. Goeckerman, dermatitis; Roger L. J. Kennedy, "Chronic Laryngeal Stridor."——Dr. Richard H. Jaffe, Chicago, addressed the Des Moines Academy of Medicine and the Polk County Medical Society, September 30, on "Visceral Changes in the Late Stages of Acquired Syphilis, with Special Reference to Syphilitic Aortitis."——The Ringgold County Medical Society was addressed, September 18, at Mount Ayr, by Dr. Fred Moore, Des Moines, on "Infant Feeding."——The Dubuque County Medical Society was addressed at its annual meeting, September 23, by Dr. Nelson M. Percy, Chicago, on "Appendicitis and Intestinal Obstruction," and Clarence W. Baldridge, Iowa City, "Recent Developments in Diseases of the Blood";

a motion picture of "Management of Breech Presentation" was presented by Dr. David A. Horner, Chicago.——Dr. William M. Rohrbacher, Iowa City, spoke on "Use of Ultraviolet Ray in Vincent's Angina" before the Johnson County Medical Society, July 2.

KENTUCKY

Society News.—The Daviess County Medical Association was addressed, September 9, by Drs. Isaac J. Hoover, "Use of Sodium Amytal as an Anesthetic Agent," and Francis M. Sherman, Owensboro, on "Indications, Contraindications and Complications of Ethyl Anesthesia."——The Letcher County Medical Society was recently addressed at Jenkins by Drs. Robert L. Kelly, Louisville, on "Syphilis and Its Treatment"; Albert G. Rutherford, Welch, W. Va., "Head Injuries," and William W. Nicholson, Louisville, "Summer Diarrheas."——Physicians of Graves, Calloway, Hickman and Fulton counties were addressed, September 30, among others, by Dr. Arthur G. Quinn, Memphis, Tenn., on "Diseases of the Thymus Gland in Infants."

MARYLAND

Personal.—Dr. Thomas S. Cullen, professor of clinical gynecology, Johns Hopkins University School of Medicine, Baltimore, was presented with the degree of doctor of laws by the University of Toronto at a special convocation, September 16, in connection with the opening of the Banting Research Institute. The honor was conferred in recognition of Dr. Cullen's work on cancer. He graduated as a silver medalist from the University of Toronto forty years ago.

Hospital News.—The new addition and the added facilities at the Emergency Hospital, Annapolis, were completed, October 1, and will give the hospital 100 beds and double its present capacity. This hospital is affiliated with the Johns Hopkins Hospital, Baltimore, and the Sheppard and Enoch Pratt Hospital, Towson; a two months' course in pediatrics is studied at Johns Hopkins Hospital and a three months' course in psychiatry at the Sheppard and Enoch Pratt Hospital.——The discovery of a kitchen helper connected with the preparation of food for employees in the Johns Hopkins Hospital, who was a "walking typhoid case," was recently reported.——The new hospital at Fort George G. Meade, with accommodations for 100 patients, has been completed at a cost of $243,233.

County Health Service in Maryland.—Dr. William S. Keister has been transferred from Prince Georges County to become full-time health officer for Baltimore County with headquarters at Towson, and Dr. Archie B. Hooton will be full-time health officer for Prince Georges County with headquarters at Upper Marlboro. Dr. Hooton has been in charge of the health unit in Darlington County, S. C., for the past eight years. Dr. Robert H. Riley, director, state department of health, stated that arrangements are under way for the appointment of a full-time health officer for Anne Arundel and Washington counties. When this is completed, fourteen counties, having a population of 653,000, or four fifths of the total population of the counties, will have full-time health service. Six of the remaining counties—Caroline and Dorchester, Charles and St. Mary's, and Somerset and Worcester—with a population of 120,527, or 14 per cent of the total population of the counties, are grouped into sanitary districts with a full-time deputy state health officer in charge of each district. The three counties with part-time service, Garrett, Howard and Queen Anne's counties, have a combined population of approximately 50,000 and constitute 6 per cent of the total population of the counties. Dr. Riley states that the goal set for the state is full-time health service for each county corresponding to the full-time educational service which is already established for each county.

MASSACHUSETTS

Dr. Knoop Gives Dunham Lectures.—Dr. Franz Knoop, professor of physiologic chemistry and director of the Institute for Physiological Chemistry, University of Tübingen, will deliver two lectures at the Harvard Medical School, October 15 and 17, at 5 o'clock, under the Edward K. Dunham Lectureship for the Promotion of Medical Sciences; the subject will be "Intermediary Metabolism."

Society News.—The Berkshire District Medical Society was addressed, September 19, by Dr. Edward A. Archibald, professor of surgery at McGill University Faculty of Medicine, Montreal, on "Indications for Surgery in Pulmonary Tuberculosis."——The New England Surgical Society, at its annual meeting, September 26-27, at Boston, was addressed by Drs. Richard S. Benner, Springfield, "Uterine Fibroids and Pregnancy"; Carleton R. Metcalf, Concord, N. H., "Atelectasis"; Daniel C. Patterson, Bridgeport, Conn., "A Case of Kohler's Disease"; Emery M. Fitch, Claremont, N. H., "Some Causes of Failure in the Operative Treatment of Inguinal Hernia"; Thomas N. Hepburn, Hartford, Conn., "Denervation and Displacement of the Ureter for Kidney Colic"; Paul P. Swett, Hartford, Conn., "Fractures of the Head of the Tibia Entering Into the Knee Joint," and Frederic J. Cotton, Boston, "Notes on Tumors and Near Tumors of Bone." A symposium on the vascular lesions of the extremities and a series of clinics were included in the program.

MICHIGAN

Personal.—The championship of the annual golf tournament of the Wayne County Medical Society, September 10, was won by Dr. Frank A. Kelly; the handicap championship was won by Dr. Wesley J. Reid.——Dr. Frederick Williamson was appointed health officer of Ypsilanti, September 15, to succeed Dr. Matthew E. Soller, who resigned to be connected with the extension department of health of the University of Michigan.

Society News.—At the annual golf tournament between the Kalamazoo Medical Academy and the Calhoun County Medical Society, the silver tournament cup was won by Kalamazoo physicians.——Drs. John H. McRae and Richard R. Smith, both of Grand Rapids, spoke on "Experience of Eye Work in India" and "Travelogue and Experience in India," respectively, before the Montcalm and Ionia County Medical Society at Belden, September 9.

Entrance Requirements Raised at University of Michigan.—Added entrance requirements in the University of Michigan Medical School, which will demand nearly a year of extra preparatory work, were announced, September 23, according to the Chicago *Tribune*. Candidates for the M.D. degree will be required to take ninety instead of seventy hours of credit, and one third instead of one fourth of their grades for entrance must be B's. The new ruling, it is reported, will be effective next fall.

MINNESOTA

Society News.—Dr. J. Theodore Schlesselman, Mankato, was elected president, and Dr. Monte C. Piper, Rochester, secretary of the Southern Minnesota Medical Association at its recent annual meeting.——The Chisago-Pine County Medical Society was addressed at Pine City, August 26, by Drs. Carleton G. Kelsey, Hinckley, on "Eczema of the Scrotum"; William T. Pearson, Finlayson, "Various Methods of Tonsillectomy"; Egbert J. Borgeson, Minneapolis, "Relation of Nose and Throat Infections to the Chest," and Francis F. Callahan, Pokegama, "Collapse Therapy," illustrated.

MISSISSIPPI

Tennessee Teachers to Assist Mississippi School of Medicine.—In the reorganization of the faculty of the School of Medicine of the University of Mississippi, assistance will be given by William R. Amberson, Ph.D., head of the department of physiology, University of Tennessee Medical School, and his assistants. Dr. Amberson and Arthur G. Mulder, Ph.D., will deliver special lectures, and Frederic R. Steggerda will stay in charge of the classes. Dr. Philip L. Mull, professor of anatomy, has assumed the duties of dean.

NEBRASKA

State Fair Health Program.—The health department at the Nebraska State Fair conducted by the Nebraska State Medical Association was conducted by 132 physicians this year. Periodic health examinations were given to 412 babies and children, 199 adults; eight prenatal examinations to expectant mothers, and examinations of thirty-two 4-H Club boys and girls. These examinations revealed that 91 per cent of the adults and 80 per cent of the children had defects in need of medical attention. Of the 412 babies and children examined, only 63 had been vaccinated. In the 109 audiometer tests for acuity of hearing, the average hearing loss was 9 per cent. In the system used, all examination records are sent to the family physician designated by the patient, and the patients and parents are notified to call on their physician for interpretation of the record and advice regarding treatment. The state medical association had charge of all health displays and demonstrations, which were under the direction of Dr. Edward R. Hays, Falls City, chairman of the Public Activities Committee, who has also been made superintendent of health on the state fair board. The department occupied all of the building formerly designated as the women's building. The association operated a roentgen-ray and clinical laboratory, a large room for exhibits, and a theater which was used for lectures and motion pictures. They supervised also the emergency hospital, which cared for cases of acute illness and injury. The supervision of health activities was started in 1929 (The Journal, July 29, 1929, p. 215).

NEW JERSEY

Society News.—The Atlantic County Medical Society will be addressed, October 10, at Atlantic City by Dr. Edward A. Strecker, Philadelphia, on "The Psychology of the Normal Child."——The Morris and Warren county medical societies were addressed at Bernardsville, July 16, by Dr. Richard Kovacs, New York, on "Physical Therapy in General Practice."

NEW YORK

Society News.—The First District Branch Medical Society will be addressed, October 7, at the Academy of Medicine, New York, by Drs. Elliott P. Joslin, Boston, on "Symptomatology and Treatment of Diabetes"; Frank H. Lahey, Boston, "Toxic Goiter," and John J. Moorhead, New York, "Fractures."——The Medical Society of the County of Nassau was addressed at Hempstead, September 30, by Dr. Richard Kovacs, New York, on "Use of Diathermy in Medicine and Surgery," illustrated.

New York City

Much Less Diphtheria. — Figures recently made public, *disclosed a reduction of 57 per cent each in diphtheria cases* and deaths in the city in the first eight months of 1930 as compared with the corresponding period of 1929. There were 3,003 cases of diphtheria, as compared with 7,020 in the corresponding period of last year. There were 158 deaths, as against 374 in the first eight months of 1929. It is reported that the case decrease of 4,017 and the mortality decrease of 216 sets a new record in toxin-antitoxin work. The Diphtheria Prevention Commission of the department of health has been conducting an intensive campaign against diphtheria for twenty months.

OHIO

Society News.—The Summit County Medical Society will be addressed, October 7, at the Akron City Club by Dr. John A. Kolmer, Philadelphia, on "The Serology and Treatment of Syphilis."——The commissioners of Portage County have under consideration the gift offered by the heirs of Judge and Mrs. George F. Robinson, which include the Robinson homestead and $50,000 in cash, the cash to be used with county funds for the building and equipment of a new hospital. A bond issue of $75,000 is said to be contemplated to carry the project through.——The Muskingum Academy of Medicine and the district dental association met jointly, September 10, at Zanesville and were addressed by Dr. Hugh W. MacMillan, Cincinnati, on "Oral Surgery," and Dr. Beatrice A. T. Hagen, Zanesville, anesthesia.

OKLAHOMA

Society News.—The Jefferson County Medical Society was addressed, July 7, at Waurika, by Drs. W. M. Browning, on "Rational Treatment of Abortion"; Clinton M. Maupin, "Use of Digitalis and Strophanthus in Heart Affection," and James I. Hollingsworth, "Uterine Atresia," with report of a case. ——The Tulsa County Medical Society was addressed, September 22, by Dr. Samuel C. Shepard on "Erysipelas, a New Method of Treatment."

OREGON

Society News.—A new medical journal, called the *Western Journal of Surgery*, has started publication in Portland. Dr. Goodrich C. Schauffler, the editor, states that the *Journal* will be devoted to unifying surgical interests of the western coast by publication of suitable papers, discussions, reports of surgical meetings and allied gatherings.——The Lane County Medical Society, cooperating with the Southern Willamette District Dental Society and the Lane County Graduate Nurses Association, maintained an exhibit during the Lane County fair at Eugene, August 27-30, which featured displays on periodic health examinations, dental health, quackery, and *Hygeia.*——The annual conference of city and county health officers was addressed, September 16-19, among others, by Drs. Benton C. Wilson, Medford, on "The Full-Time Health Unit"; Bertram R. Shoemaker, Roseburg, "Preventive Pediatrics"; William Levin, D.P.H., Portland, "Skin Test for Immunity and Diagnosis"; Clarence J. McCusker, Portland, "Reducing Maternal Mortality," and Paul M. Drake, Coquilla, "Diphtheria Control."

Personal.—A complimentary dinner was tendered Dr. John F. Dickson, August 28, on the occasion of his seventy-fifth birthday, by the Pacific Coast Oto-Ophthalmological Society.

TENNESSEE

University News.—The location of the new Meharry Medical College will be near Fisk University in North Nashville, with which the medical school will cooperate, but there will be no connection between the managements of the two institutions and each will keep its own identity. It is said that the new plant is to cost $2,000,000. During the past year 2,160 patients were treated in the hospital, of which 1,928 were charity and 14,103 cases were treated in the clinics.

Society News.—The Nashville Academy of Medicine was addressed, September 23, by Dr. Jefferson C. Pennington on "Significance of Urethral Discharge in the Male." The academy was addressed, September 16, by Dr. Charles Sidney Burwell on "A Clinical Study of Adhesive Pericarditis."——The Tri-County Medical Society, comprising McMinn, Monroe and Loudon counties, was addressed, September 18, at Lenoir City, by Drs. Robert C. Kimbrough, Madisonville, on "Pneumonia"; James B. McElroy, Memphis, "Ascites," and James G. Eblen, Lenoir City, who talked on "Some Diagnostic Points on Diseases in Infancy and Early Childhood."——The Bedford County Medical Society was addressed, August 21, by Dr. John W. Sutton, Petersburg, on colitis.——Dr. Jarrell Penn, Memphis, addressed the Gibson County Medical Society, September 29, on "The Commoner Orthopedic Conditions," and Dr. G. Weldon Oliver, Medina, on "Pernicious Vomiting of Pregnancy."——The Hamilton County Medical Society was addressed, September 4, by Dr. Robert C. Robertson, Chattanooga, on "Aspects of Low Back Pain: Report of Three Cases"; Dr. Olango G. Hughes addressed the society, September 11, on eclampsia.——"The Early Correction of Cross-Eyed Deformities" was the subject of Dr. David Bruce P'Pool, Nashville, among others, before the physicians of Hardin, Lawrence, Lewis, Perry and Wayne counties at Hohenwald, August 27.——The Coffee County Medical Society was addressed, September 9, at Manchester, by Dr. Charles E. Evans, Tullahoma, on "Artificial Feeding of Babies."——The Tri-County Medical Society (Carroll, Weakley, Henry and Benton) was addressed at Huntington in September by Drs. William W. Wilkerson, Jr., on "Foci of Infection"; Emmett E. Brown, Nashville, "X-Ray Diagnosis of Pulmonary Tuberculosis," and Virgil E. Massey, Huntingdon, "The Importance of a Careful History."

TEXAS

New Children's Hospital and School.—A new children's hospital, constructed by the state as a unit of the state tuberculosis sanatorium at Sanatorium was ready for occupancy, October 1. The hospital, which will accommodate 161 patients, is two stories high, 406 feet long and 60 feet wide. A feature in connection with the institution is that an eleemosynary independent school district has been formed at the sanatorium with an affiliation of the state department of education. This will afford children in the district to continue school work from the first to seventh grades inclusive. The institution is also provided with a completely equipped playground. Applicants admitted to the sanatorium are given six months' treatment; an additional three months will be extended the patient if the superintendent deems his physical condition can be found improved by this additional time. The institution will accept only children with early pulmonary or glandular tuberculosis; cases in the advanced stage of tuberculosis cannot be accepted by law. Cases of tuberculosis of bones and joints are referred to the John Sealy Hospital at Galveston.

Society News.—The Dallas Eye, Ear, Nose and Throat Society recently gave a banquet in honor of Dr. Viktor Frühwald, University of Vienna.——The Dallas County Medical Society was recently addressed by Drs. Claude E. Watson, Dallas, and Edgar Hull, Pleasant Hill, La., on "Latent Malaria" and "Management of Hypertension," respectively.——Dr. Martin L. Wilbanks, Greenville, addressed the July 8 meeting of the Denton County Medical Society on "Public Health Laws as They Pertain to Vital Statistics." Texas physicians are endeavoring to secure registration of 90 per cent of births and deaths, which is required before the state can be included in the registration area.——Dr. Allen T. Stewart, Lubbock, addressed the Lubbock-Crosby Counties Medical Society, July 1, at Lubbock, on "Eclampsia."——"Progression in Medicine" was the subject of Dr. Moses Thompson, Weatherford, before the July 1 meeting of the Parker County Medical Society.——The program of the Southwest Texas District Society, July 22-23, included addresses by the following San Antonio physicians: Harry McC. Johnson, Jr., "Diagnosis and

Treatment of Renal Tumors"; Omer M. Roan, "Intussusception of the Small Intestine Caused by Benign Tumors"; L. P. Guttman, Corpus Christi, "More Efficient Fracture Surgery by Local Anesthesia and Functional Therapy," and John V. Blair, Corpus Christi, "Endothermic Surgery as a Factor in the Treatment of Malignancy."

GENERAL

Qualifications of Nurses.—More than 4,000 physicians recently replied to a questionnaire sent out by a committee on the grading of nursing schools, as to what qualifications a nurse should have; 65 per cent of these physicians replied "skill in general care" was the requisite of a good nurse; 65 per cent wanted one that could make the patient comfortable; 45 per cent wanted one skilful in observing and reporting symptoms; 43 per cent preferred a nurse careful in following medical orders; 34 per cent said good breeding and attractive personality come first; 30 per cent skill in handling people; 28 per cent skill in asepsis; 27 per cent familiarity with hospital routine; 21 per cent familiarity with their personal methods; 15 per cent, ability to work under a heavy strain; 15 per cent, familiarity with a particular disease; 3 per cent said she should be able to take charge of the family, and 3 per cent that she should be a mother's helper and houseworker. The study shows that the demand for practical nurses is dropping. Nine out of ten physicians reported they were getting the nurses they wanted. The surgeons were the group most satisfied.

Thousands of Cases of "Jamaica Ginger Paralysis."—The U. S. Public Health Service recently announced that tri-ortho-cresol phosphate has been determined to be the probable cause of the recent "ginger jake" epidemic. The chemical is said to be widely used in the liquor and leather industries. It is colorless, odorless and capable of causing paralysis and death in the case of persons who have consumed it in alleged fluid-extracts of ginger, popularly called "ginger jake." Chemists assert that alcohol with a paralysis-producing adulterant has been used by underworld liquor manufacturers in order to make ginger extract drinkable and cheap, but deny that it could have been used as a government denaturant. According to the public health service, information received from forty-seven state health officers showed that 4,837 cases of jamaica ginger paralysis have been officially reported. It is estimated, however, that many cases were not reported officially. It is understood that the director of the bureau of prohibition of the department of justice estimates that approximately 20,000 cases of this condition have occurred in the United States. July 29, it was reported that twenty-one men, including eighteen from New York City and Brooklyn and three from Kansas, and six Brooklyn and New York corporations were indicted for conspiracy to violate federal laws following an investigation into the manufacture, distribution and sale of adulterated jamaica ginger.

Society News.—The examination of the American Board for Ophthalmic Examination will be held at the Illinois Eye and Ear Infirmary, Chicago, October 27; Dr. William H. Wilder, 122 South Michigan Avenue, Chicago, is secretary of the board.——Drs. Frank H. Ewerhardt, St. Louis, Mo., and Frederick L. Wahrer, Marshalltown, Iowa, were elected president and secretary, respectively, of the American Congress of Physical Therapy for 1931-1932 at its recent annual meeting.——The annual meeting of the Association of Medical Record Librarians of North America will be held in Philadelphia, October 13-17.——The western meeting of the National Academy of Sciences, September 18, at Berkeley, was addressed by Drs. L. Frederick Reichert, San Francisco, on "Importance of Circulatory Balance in Survival of Replanted Limbs"; Carl L. A. Schmidt, Ph.D., San Francisco, "Relation of Bile to Intestinal Absorption of Vitamin A in the Rat," and David L. Webster, Ph.D., Stanford University, Calif., "Effects of Rediffusion of Cathode Rays on X-Ray Structure."——Officers elected at the annual meeting of the Aero Medical Association in Chicago, August 29-30, were Drs. Louis H. Bauer, Washington, D. C., president; Ralph N. Greene, Jacksonville, Fla.; Frederick C. Warnshuis, Grand Rapids, Mich.; Charles H. Gowan, Glendale, Calif.; Harold M. Camp, Monmouth, Ill., and John A. Tamisiea, Omaha, vice presidents, and William B. Smith, Hartford, Conn., secretary. The program consisted of papers by Major Raymond F. Longacre, U. S. Army, presented by Dr. Harold J. Cooper, Washington, D. C., on "Factors in Examination of the Nervous System in Pilots"; Dr. Albert J. Herbolsheimer, Minneapolis, "Certain Factors in Examination of the Eyes of Aviators"; Dr. Greene, Jacksonville, "Practical Suggestions by a Pilot-Flight Surgeon," and Dr. Bauer, "Certain Aspects of Blind Flying."

FOREIGN

British Medical Association Prize.—The council of the British Medical Association proposes to award in March, 1931, the prize of £25 for the best essay attempting to "describe and discuss cases illustrating the modern methods of diagnosis of early pulmonary tuberculosis." The essay must be written by a final year medical school student or registered medical practitioner of not more than one year's standing; either of whom must be studying or must have studied at one of the medical schools in the British empire outside the British Isles. The essay must reach the medical secretary, British Medical Association House, Tavistock Square, London, W. C. 1, not later than Jan. 12, 1931.

Society News.—The thirty-ninth French Congress of Surgery will be held in Paris, October 6-11. Subjects to be discussed are: pancreatitis, introduced by Pierre Brocq of Paris, and Miginine of Toulouse; traumatic spondylitis (Kummel-Verneuil disease), introduced by Froelich of Nancy and Albert Mouchet of Paris, and preparation of patients for operation, introduced by Lombret of Lille and Sauve of Paris.——The State Institute of Public Health of Oslo, which was formally opened, August 16, includes three buildings equipped with the most modern apparatus for the speedy and exhaustive treatment of illness, and laboratories for research and for dealing with the spread of disease. The total cost of the buildings was about £195,000, of which the state contributed £83,000 and the Rockefeller Institute £61,000.——The annual meeting of the German Society for Light Research was held in conjunction with the German Hygiene Society in Dresden, September 5-7.——The twentieth Congress of the Italian Society of Laryngology, Otology and Rhinology will be held in Sardinia, October 15-23. Further information may be obtained from Prof. Deodato De Carli, Clinica Otorino-laringologica, Ospedale Gesu E Maria, Naples.——The thirtieth French Congress of Urology will be held at the Paris Faculty of Medicine, October 7. A discussion of renal contusions and their remote sequels will be introduced by Dr. Gérard of Lille.——The Society for Digestive and Metabolic Diseases will hold its tenth annual meeting in Budapest, October 6-8.

CORRECTION

Tuberculosis in England.—The statement of the London correspondent in The Journal, August 2, that every week 70,000 cases of tuberculosis were notified in England and Wales was erroneous. The Ministry of Health has called attention to the fact that 70,000 cases are approximately the number notified in the course of a year.

Government Services

Change of Station in the Navy

The following changes of station in the navy have recently been announced: Lieut. John G. Smith, to the naval hospital, Newport, R. I.; Lieut. William S. Cann, to division 10, destroyer squadron; Lieut. Frederic W. Farrar, to the U. S. S. *Dobbin;* Lieut. Charles W. Shilling, to division 42, destroyer squadron, scouting fleet; Lieut. Comdr. David Ferguson, to the Navy Yard, Pearl Harbor, T. H.; Lieut. John P. Wood, to the Naval Hospital, Great Lakes, Illinois; Lieut. Richard B. Blackwell, to the marine recruiting station, Philadelphia; Lieut. Carr E. Bentel, to the Asiatic Station.

Army Personals

Lieut. Col. William S. Shields, from Fort Sam Houston, Texas, to Fitzsimons General Hospital, Denver; Major Luke B. Peck, having attained the age of 64 years, is retired from active service and placed on the retired list with the rank of lieutenant colonel; Major Philip P. Green, on completion of his present tour of foreign service, will be assigned to duty at Fitzsimons General Hospital; Lieut. Col. Henry C. Coburn, Jr., from Fitzsimons General Hospital to Fort Sam Houston, Texas; Major Clyde C. Johnston, from Selfridge Field, Mount Clemens, Mich., to Kelly Field, Texas; Major Brown S. McClintic, from Fort Benjamin Harrison, Ind., to Fort Sheridan, Ill.; Capt. James A. Ramsey, from the St. Louis Medical Depot, St. Louis, to Fort Sam Houston, Texas; Major Joseph C. Breitling, from Fort Lewis, Wash., to Chilkoot Barracks, Alaska.

Foreign Letters

LONDON

(From Our Regular Correspondent)

Sept. 13, 1930.

The Socialization of the Medical Profession

In a previous letter (The Journal, August 16, p. 543) the adoption by the British Medical Association of a scheme in which a full medical service is to be provided by the state for every person, i. e., the completion of the socialization of the medical profession, was described. It was explained that such socialization was desired neither by the profession nor by the association, but that in the present socialistic phase of British politics such a development was thought inevitable and that it was held to be better for the profession to bring forward a scheme than to have one imposed on it. But this momentous decision is viewed with considerable misgiving by a large minority of the profession, including those who have always regarded the national insurance act as anathema. Their objections were ably voiced by Dr. Graham Little, a dermatologist, who is member of parliament for London University and therefore a prominent figure in medical politics. In an address to the Paddington Medical Society he said that the profession was at the parting of the ways and decisions were about to be taken even more important than that of 1912, when that great step in medical socialism, the national health insurance scheme, came into operation. This was copied by Mr. Lloyd George from the German scheme, and it is interesting to recall that after prolonged discussion it was rejected by the British Medical Association as detrimental to the interests and honor of the medical profession. Then came the coup of Lloyd George who, by increasing the capitation grant, caused a number of physicians to break away from the combination and thus overcome the resistance. Dr. Little described the issue as none less than whether the profession should consent to the extermination of private practice and to the substitution for it of practically universal contract service or universal state medical service. The difference between the two alternatives might not be great, for if contract practice became universal the state would dominate as much as it would any state medical service. He had information that the present socialist government had in preparation a scheme for a state medical service with influential support. The rumor of this had clearly influenced those who controlled the British Medical Association. At the representative meeting resolutions promoted by the council recommending the institution of what amounted to a general panel for the nation, were passed by large majorities. This was brought about by representations by leading members of the council that the alternative for the profession was not private practice or contract practice, because private practice was no longer a tenable proposition, but that the choice lay between the policy promoted by the association and a State service. This policy, said Dr. Little, would bring seven eighths of the whole population into the panel, and private practice would become too precarious to survive for any time. Further, the national health insurance fund was practically bankrupt. It had never been able to furnish the services which the government commission had declared ought to be given — institutional and specialist treatment. Would universal panel practice improve the status of the profession or the conditions of life of the physician? It would be conducted under the continual harassment of outside control. At present the physician had to satisfy patients; under the new régime he would have to satisfy an administrative superior, whose first consideration would seldom be the patient. Medical insurance encouraged recourse to the physician when unnecessary and, as people did not prize what they did not pay for, the services of the physician were less valued. By our system of doles and mollycoddling we were converting our people into loafers and hypochondriacs.

Dr. Little's address has made a great stir and has received lengthy notices in the daily press, by which the belief is expressed that for some time the government has intended to nationalize the medical profession and that alarm caused by this rumor has led the British Medical Association to formulate its scheme. In a press interview with the *Star*, Dr. Little said that he had no doubt that before we realize it we shall have foisted on us an unworkable scheme of automatic medical treatment, good neither for the patient nor for the physician, who would become a civil servant working so many hours a day, with no incentive to become more useful to the world and probably with no opportunity of doing so. But he admitted that the younger generation of physicians might prefer a regular life of work and leisure and a regular income. The *Star* representative could not find any one who could suggest how state doctoring would work out in practice. Would it be illegal to fall ill outside certain prescribed hours? Would the physicians work in shifts and if so what would be the position of the patient who called in his physician three times during the day and night and found himself in the hands of three different men?

Sir Ronald Ross

"Probably the greatest genius living in our times" was the description of Sir Ronald Ross by Sir Aldo Castellani, director of tropical medicine at the Ross Institute. The occasion was a luncheon at the institute to celebrate the death thirty-three years ago of the mosquito in which Sir Ronald Ross discovered the infectious agent of malaria. Sir William Simpson, director of tropical hygiene at the institute, said that Ross's discovery would always be memorable in preventive medicine. It had saved millions of lives and was bound to save millions more. It was the work of a genius who did not confine himself to medicine but was also a poet and mathematician. But the one thing he could not do was to make money. The British government had treated him shabbily in conferring no reward on him, as had been done on Jenner. Sir James Barr said that because of this refusal a fund had been raised by private subscription, which was still growing. Amid laughter he recalled how an American admirer of Ross's poetry had cabled to the prime minister asking him to appoint Ross poet laureate, when the appointment recently became vacant by the death of Bridges. An American physician, Dr. Robert Pitfield, said that by this time next year America would have contributed several thousands of pounds to the fund. Sir Ronald, who is 73, was looking remarkably well. The hymn of praise, written by him in India after his great discovery, was printed on the menu.

Physiologic Observations on the Kanchenjunga Expedition

The recent attempt to climb one of the highest mountains in the world, Kachenjunga (28,150 feet), resulted in certain observations of physiologic importance. Altitude was found to impair digestion, so that a careful choice of food had to be made. At heights over 20,000 feet, light sugary foods were found most suitable, such as jams, biscuits, chocolate, sugar, canned fish and fruit, and condensed milk. A little alcohol was found to be a great aid to digestion. Hot rum at bedtime was found the best drink to promote sleep. The general health of the expedition was cared for by Dr. Richter who attempted to combat the deleterious effects of altitude by bloodletting, as he considered that the relation of the normal blood pressure to the low pressure of the atmosphere was responsible for headache and mountain sickness. Only two members of the expedition submitted to having 200 cc of blood withdrawn. As they were both subsequently taken ill it was considered doubtful whether the experiment resulted in any good. More successful was the daily administration of liver in the form of pills, to assist in the increased formation of hemoglobin, which takes place as part of acclimatization at high altitudes. Though oxygen should be carried on such expeditions for medical purposes, its use to assist climbing at high altitudes was not a success. It stimulated the body for a short time but the subsequent reaction was severe. The weight of the apparatus prohibited prolonged use and by tiring the climber neutralized the good effects. The secret of high climbing was found to be slow acclimatization, which was best effected by living as comfortable as possible at a height of 20,000 feet. Here appetite is unimpaired and sound sleep is possible.

The Origin of the Alphabet

In the Section of Anthropology of the British Association, Sir Richard Paget, who is well known for his studies of the positions of the lips, tongue and mouth in producing sounds and for the production of working models which reproduce these sounds, developed further the old theory that the development of alphabets has been influenced by sympathy between the human mouth and tongue and the human hand. As long ago as 1667, von Helmont put forward this theory with respect to the Hebrew alphabet. In 1902 Mr. Rudyard Kipling, probably independently, suggested mouth-shaped origins for the letters a, o, u, m and g. Sir Richard Paget pointed out that the alphabet was generally supposed to have been derived by simplification of preexisting pictographs, by adopting the picture of some word beginning with a given vowel or consonant as the alphabetic sign for that vowel or consonant. Thus the alpha of the Greeks was derived from the Egyptian sign called "alf," which represented the head of an ox with his horns. But the difficulty arises that there were in Egyptian at least fifty hieroglyphs for words beginning with the letter a. Sir Richard Paget suggested that the early scribes, in their search for suitable symbols, were unconsciously affected by a sympathy of movement between their tongues and mouths and their hands; they therefore selected those pictographs in the drawing of which the hand followed a direction which most closely followed the track of the tongue and lips in uttering the sound in question. He found evidence of this sympathy even in the Sumerian cuneiform writing. He gave examples from our own alphabet of the shape of letters representing the position of the mouth and lips in forming the sound.

Herbert William Carson

The death at the age of 59 of Mr. H. W. Carson removes a surgeon who was well known to Americans because of his work in postgraduate teaching. He was one of the organizers of the London meeting of the Interstate Medical Association and in 1929 he delivered the Mütter lecture to the College of Physicians of Philadelphia, in which he dealt exhaustively with intestinal obstruction from the historical, clinical and operative standpoints. Educated at St. Bartholomew's Hospital, he was appointed assistant surgeon to the Prince of Wales's Hospital, Tottenham (in north London) where he combined ear, nose and throat with general surgery. He was active in the organizing and subsequent working of the North East London Post-Graduate College, which was formed in connection with his hospital, and later in the work of the fellowship of medicine. He was especially concerned with the overseas part of the work of the fellowship and visited Canada in order to inform himself of the needs of physicians there. He became chairman of the executive committee of the fellowship and was appointed to the provisional organization committee of the new British Postgraduate Hospital. He was best known as an abdominal surgeon and edited and largely contributed to "Modern Operative Surgery," published in 1924. He edited also the tenth edition of Pye's "Surgical Handicraft." He was an indefatigable worker and lucid teacher.

PARIS

(From Our Regular Correspondent)

Sept. 10, 1930.

Titrable Forms of the Bacilli Typhosus and Paratyphosus

Studies on the filtrable forms of various micro-organisms are overthrowing many conceptions of hygiene that were regarded as definitely established, so that the whole epidemiology of many infectious diseases has to be restudied. Typhoid and paratyphoid bacilli normally do not pass through porcelain filters. Under the influence of the bacteriophage, they take on a filtrable form and later, when introduced into the organism, they again assume their bacillary form. Mr. P. Haudroy found these invisible forms in the stools and in the blood of typhoid patients, and in polluted waters. These invisible forms in polluted waters transmit typhoid and paratyphoid fevers, and the absence of bacilli in such waters will give henceforth no sense of security. The same conclusion applies to germ carriers, for they may remain for a long time infectious, though they present no visible bacilli, provided they still harbor invisible and filtrable forms. It is even probable that there are typhoid septicemias without bacillary forms in the blood.

Tuberculous Ultravirus in Blood of Patient with Tuberculids

In 1929, P. Ravaut, Valtis and F. van Deinse demonstrated the presence of tuberculous ultravirus in the lesions of papulonecrotic tuberculids and in a case of subcutaneous sarcoids. Pursuing their researches further, they have now discovered that the blood of a patient affected with papulonecrotic tuberculids, inoculated in the guinea-pig at two different times, with an interval of eight months, provokes lesions similar to those produced by the inoculation of tuberculous ultravirus. Four successive reinoculations, from animal to animal, showed in each case the presence of tubercle bacilli in the glands. This fact tends to prove that papulonecrotic tuberculids are the result of a septicemia caused by the tuberculous ultravirus. The authors conclude that these facts are evidence of the different evolution of the various types of tuberculosis of the skin, tuberculids being due to tuberculous ultravirus and lupus to the bacillary form of the Koch bacillus.

Contradictory Results from Suprarenalectomy

In a case of thrombo-angiitis obliterans, Professor Leriche of Strasbourg removed a suprarenal capsule. The result was immediate; the pains that had become intolerable ceased at once and an incurable ulceration of the great toe scarred over rapidly. During the five years elapsing since the operation, there has been no recurrence and the patient is in perfect health. There is, however, a slight claudication of the leg after the patient has walked a kilometer. Mr. Monnier-Vinard decided to apply the same operation to a subject affected with permanent arterial hypertension, in whom all forms of treatment had failed. There was only a transient and insignificant lowering of tension. The permanent result was nil. Radiotherapy of the vertebral column was also ineffective. These trials prove at least that man can live perfectly well with a single suprarenal capsule.

Trypanosomiasis in Africa

The unsatisfactory results secured in French Equatorial Africa, which is gravely infected by trypanosomiasis, are due in part to the scarcity of native workmen and in part, according to Mr. G. Muraz, to the insufficient number of physicians. A complete reorganization of the medical service has been decided on by the governor of the colony. The new trypanosomiasis service in French Equatorial Africa will comprise twenty-eight prophylaxis sectors, with twenty-one physicians, twelve assistant hygienists, nine European agents and 152 native male nurses. It will thus become possible to reach most of the persons affected with trypanosomiasis and to treat them either with atoxyl or with tryparsamide. Arsenoresistant patients must be recognized. In a limited region about Mayumbe, this arsenoresistance is extending to an ever widening area. Mr. A. Sicé publishes a number of observations with graphs showing that lumbar puncture is indispensable in trypanosomiasis patients in order to make a definite diagnosis, establish the diagnosis, and control the treatment. According to Mr. Lui, a physician who has made a special study of trypanosomiasis cannot get away from the idea of multiple indications for lumbar puncture. He has performed more than 10,000 rachicenteses in trypanosomiasis patients, this control being applied every three months the first year, every six months the second year, and then once a year. The number of leukocytes per cubic millimeter sometimes exceeds 2,000, and the albumin content may range around 2 Gm. per thousand.

First Aid at Children's Playgrounds

The public squares of Paris that serve as playgrounds for children are often the scene of slight accidents that occur during their games. A proper hygienic treatment of even small lesions serves as an excellent practical lesson for the child himself. As the nearest pharmacy may be some distance away, one often sees, in such cases, playground assistants, with the best of intentions, endeavor to cleanse the wound with a soiled handkerchief impregnated with their saliva, and cases of syphilis have been known to be transmitted in such manner. At a recent meeting of the municipal council of Paris, Mr. Georges Prade, a member of that body, requested the prefect to issue an order that the *kiosques,* which are found at all the playgrounds and at which toys and cakes are sold, shall have for sale, at a reasonable price, such articles as are likely to be needed for first-aid treatment: dressings, gauze, surgical cotton, bandages, tincture of iodine. The prefect made some objections to the request, pointing out that it is to be feared that the pharmacists' syndicate will defend the privilege of its members, who have the sole right to sell to the public all internal and external remedies.

Sept. 13, 1930.

Proposed Ethical Order of Physicians

A bill filed, April 23, 1929, with the bureau of the senate, contemplated the creation of distinct councils for the physicians, the dentists, the pharmacists and the veterinarians. The bill was discussed in The Journal, Aug. 24, 1929, p. 627. Mr. Baels, minister of the interior and of health, has filed an amended bill changing completely the first proposal and a new bill providing for the creation of an ethical order of physicians. The amended bill no longer mentions the creation of councils of physicians but provides merely for the establishment in each province of a council of pharmacists, a council of dentists and a council of veterinarians. The new bill providing for the creation of an ethical order of physicians is accompanied by a brief statement of the motives:

> The creation of an ethical order of physicians is more closely in harmony with the aspirations of the medical profession than the medical councils would be. Moreover, the new institutions such as are provided for by the new bill will stimulate, more than the medical and allied professional councils could have done, esprit de corps, fraternal spirit and discipline. This result will be still further strengthened by the creation of the superior council of the ethical order.

The principal sections of the proposed bill are as follows:

Section 1. There is hereby created, in each province, an [ethical] order of physicians, which partakes of a civil character and which will have its seat in the chief town of the province.

Section 2. The [ethical] order of physicians will consist of all doctors of medicine, surgery and obstetrics enrolled in the register of physicians. All persons domiciled in the province and authorized to practice medicine are enrolled in the register. The register of physicians is compiled annually under date of January 1 and is published before February 1.

Section 3. No one can practice medicine unless he is a member of the [ethical] order of the province in which he is domiciled.

Section 4. The physicians enrolled in the register elect by secret ballot a council of the order, which shall comprise at least five and not more than nine members and an equal number of alternates.

Section 7. The presidents of the nine councils of the order constitute the superior council of the order of physicians of Belgium. The seat of the superior council will be at Brussels. The council will elect from its own membership a president and a vice president, and it will choose a secretary.

Sections 8 and 9 establish the jurisdiction of the provincial councils and of the superior council of the order. They have jurisdiction over all infractions of medical ethics and of matters having to do with charlatans, but exclusive of questions pertaining to fees and to pecuniary interests.

Section 10. The penalties that the council of the order may impose are warning, censure and reprimand. Only the superior council of the order can suspend the right of a physician to practice medicine and that for a term not to exceed one year; only the superior council can cancel permanently a physician's license to practice, and remove his name from the register of physicians.

Section 11. The penalties cited in section 10 can be imposed only after the accused has been given a hearing or has been summoned at least twice, with an interval of fifteen days. The practitioner may use fifteen days to prepare his defense and he shall have the right to employ counsel.

Section 13. Any decision imposing a disciplinary penalty may be appealed within eight days of the date pronounced or of the signing of the decision if rendered by default.

An appeal from the decisions imposing a warning or censure is heard by the council of the order; an appeal from a decision imposing a reprimand is brought before the superior council of the order; in an appeal from a decision imposing suspension or exclusion from the medical register, the court of appeals having jurisdiction will hear the case.

Section 21. The first elections for the creation of the council of the order will be from the list of persons authorized to practice medicine in a given province and published in execution of the royal decree of May 31, 1880, reorganizing the medical commissions of the provinces.

The council of the order will prepare the register of physicians within a month after the election or after the ratification in case the election is contested.

The remaining provisions of the bill regulate various secondary formalities and leave to a royal decree the care of regulating diverse questions of practical application.

Tuberculosis of the Digestive Tract

At a meeting in connection with the Journées médicales de Bruxelles, by the Sociétés belge et française de gastroentérologie, Dr. Brohee discussed symptomatology, diagnosis and treatment of tuberculosis of the digestive tract. Tuberculosis of the digestive tract is usually subjected to a purely medical treatment, which is frequently ineffective. Patients are, as a rule, referred at a late stage to the surgeon by reason of such complications as tumor, stenosis, perforation, occlusion, diarrhea, peritonitis or fistula.

Tuberculosis of the digestive tract is most frequently secondary to pulmonary tuberculosis. It is often grafted on parasitic lesions and coincides sometimes with a neoplastic formation.

Phthisiologists should have their attention called to: (1) the frequency of complicating lesions of the digestive tract during the evolution of pulmonary tuberculosis; (2) the possibility of an early diagnosis, and (3) their amenability to rational surgical intervention, applied as soon as possible after the beginning of the specific local lesion.

Tuberculosis of the stomach, duodenum, liver, bladder and pancreas do not have any specific symptomatology. Certain hypothetic signs have, however, been suggested. It is therefore impossible, until new research has been made, to make an early diagnosis of these conditions. Fortunately, the disorders with which they may be confused are in the nature of surgical disorders. Intestinal tuberculosis, on the contrary, has benefited greatly from clinical research. The symptoms of jejunal, ileocecal and colonic tuberculosis are better known. Increasing pains, appearing in recognized tuberculous patients, cause one to suspect specific intestinal lesions. Coprologic studies are not of much help, unless in a very late stage. In recent years, radiologic studies have made it possible to set up a series of direct and indirect symptoms that permit an early diagnosis. The medical treatment has nearly always proved ineffective from the curative point of view. Surgical treatment, which has many good results to its credit, should have its indications extended. Radical operations (exeresis) should replace, more and more, palliative operations. This result will not be attained without the aid of phthisiologists and the application of the principle of an early diagnosis.

Tuberculosis and Anthracosis

In the *Revue belge de la tuberculose,* Dr. Stassen gives an account of anthracosis. Clinicians and investigators present two widely different conceptions; some refer to the impregnation of the pulmonary tissues by coal dust whereby the lungs are said to be protected against tuberculous infection; while some speak of tuberculous infection generating a black pigmentation of the lungs, without the coal dust assuming necessarily any rôle whatever in the clinical picture. This disagreement, the author maintained, is due to the fact that sufficient research has not been devoted to the working conditions of patients in the mines. In the light of experience acquired in the mine, he seeks to present the problem in its true light.

The coal dust found in the sputum of miners with anthracosis is by no means identical with the fine carbon deposit produced by lamps that smoke, which many investigators have used in the production of pulmonary anthracosis. The former has component parts of very unequal size. Some of the particles are from 150 to 160 microns in diameter, and are consequently much larger than the largest cells of the organism that might envelop them. Some particles are amorphous; others have a structure similar to that found in the lower orders of plant life. Sometimes they are composed of iron or sulphur. The miners work generally under hygienic conditions that explain the large number of pulmonary disorders among them: absence of sunlight; deficient oxygen due to poor ventilation; confined air; toxic atmosphere; repeated chills produced by the drafty and relatively cold galleries. Pharyngitis, bronchitis and pneumonia occur, causing a diminution of their mechanical means of defense against the inhalation of coal dust. Following the course of defective bronchial trunks and branches, deprived of cilia, the coal dust is deposited and gradually accumulates. The masses formed in the pulmonary alveoli and the branches of the bronchi may remain quiescent or they may be points of attraction for microbic organisms. These may cause a virulent acute infection and death as a result of pulmonary edema, or they may give rise to a slowly developing infection that will produce bronchitis, pleuritis, areas of condensation or pulmonary cavities.

Nevertheless, tuberculosis is extremely rare in miners with anthracosis. In 1,204 miners having chronic respiratory disorders, examined since 1924 at the Dispensaire de l'espérance or at the Institut provincial de physiopathologie du travail, in Liége, the results were as follows:

	Number of Cases	Per Cent
Chronic bronchitis, with acute and repeated attacks.	688	57.0
Bronchitis; tuberculosis suspected but not confirmed	31	2.5
Chronic bronchitis, emphysematous at the start.....	196	16.5
Chronic asthmatic bronchitis.....................	99	8.5
Chronic emphysematous confirmed bronchitis.......	134	11.0
Cardiac disorders with pulmonary stasis..........	9	0.7
Pulmonary tuberculosis (bacilli in sputum)........	13	1.0
Pulmonary sclerosis following absorption of dust...	11	1.0
Pulmonary sclerosis resulting from intoxication by gases	7	0.5
Anthracosis (black sputum)......................	12	1.0
Bronchiectasis, pulmonary gangrene.............	4	0.3

Malignant Tumors in the Congo Natives

Contrary to the usual belief, there is no immunity to cancer among the black races. While malignant tumors are more rare, better organized medical research has revealed an increasing number of cases. Dr. Guillot (Belgian Congo) recalls the statistics published by Dr. Mouchet in 1926, which contain accounts of thirty-four malignant tumors found by physicians working among the natives of various regions of the Congo. Of these thirty-four tumors, one was a mixed tumor, twenty-one were epithelial and twelve were of the connective tissue. Six observations published by the author bear out this proportion of epithelial tumors with relation to tumors of the connective tissue, and confirm the conclusion of Dr. Mouchet that the black race, far from being refractory to cancer, presents all the forms of tumors encountered in the white race.

International Exposition of Dental Hygiene

The International Exposition of Dental Hygiene was organized in connection with the session at Brussels of the Fédération dentaire internationale. The purpose of the exposition was to show the methods of instruction with respect to dental hygiene and dental prophylaxis and to bring out the results secured in the countries in which these methods have been applied. The most important sections were those of Scandinavia, the Netherlands, Germany and England. The Scandinavian exhibit was remarkable. Prepared by an ardent advocate of dental hygiene, Dr. Brun of Oslo, it served as an exemplification of technical methods and publicity measures and brought out the great progress made in Scandinavian countries in combating the social evils growing out of dental disease.

Germany's exhibit consisted essentially of a traveling museum of dental anatomy and pathology, for the use of schools and centers for popular education. Wall maps showed the development of dental clinics and hygienic centers in Germany.

The Netherlands presented, in addition to a traveling museum similar to that of Germany, various publicity devices: posters, drawings, photographs and transparencies.

England sent representatives of the Dental Board of the United Kingdom, together with a complete traveling museum, publicity tracts and posters.

The University of Bonn sent an interesting series of wax molds, or casts, pertaining to the prophylaxis of the gums; also fixed prostheses and illustrative of methods of treating maxillary malformations.

France was represented by exhibits from the cities of Strasbourg and Saint-Etienne, and by the dental dispensary of the Ecole odontotechnique de Paris.

The Belgian exhibit was prepared under unfavorable circumstances. In matters of dental hygiene and prophylaxis, we are not abreast of other nations. Nevertheless, the organizers of the Belgian exhibit succeeded, after difficulties, in collecting some interesting material. The army medical service presented photographs of its hospital dental clinics. The Association générale des dentistes de Belgique displayed the activities of the dental school and dispensary.

JAPAN

Aug. 1, 1930.

A Method for Vaccination Against Smallpox

A new method for vaccination against smallpox, which will leave no trace on the skin, has been contrived by Dr. H. Yaoi, a bacteriologist in the government institute for infectious diseases. In 1924 he began to study the cause of smallpox in cooperation with Mr. H. Kasai, a veterinary surgeon in the institute. The results of the vaccine injected in 500 cases have been excellent.

A Census of Infectious Disease

The second general census is to be taken, October 1, and the sanitary bureau of the home ministry has directed that, in case of infectious disease, data will be collected by the police. The main purpose of the census is to obtain statistics on unemployment and the causes of the deaths in each family.

Trachoma Among Immigrants

A conference was held in Tokyo to investigate the trachoma problem of immigrants, especially those from Brazil. The committee consisted of the authorities from the four departments of the cabinet: the interior, foreign affairs, plantation and communication. It was decided to deliver a citation to the local governments to the effect that the health officers there should make more careful physical examination of the immigrants and that passports should not be issued without strict examination.

Children Born in the Year of the Earthquake

It is worthy of noticing from a medical point of view the results of the physical examination of the children born in Tokyo in the year of the great earthquake in 1923. The Tokyo authorities undertook to investigate the influence, mental and physical, caused by the disaster on the poor children. For this purpose 30,474 children were examined; 0.59 per cent are poorly developed mentally, and 0.28 per cent physically; 14,981 of the children, or 49.16 per cent, are diseased, 640 of whom have swollen cervical glands, 2,026 carious teeth. Generally speaking, the number of children weak mentally and physically is larger, though not considerably larger, than that of the years before.

Meetings

Dr. S. Horiguchi, captain surgeon, will be sent as delegate to the thirty-eighth general meeting of the Army Military Surgeons Association of the United States, which will be held in Washington, September 25.

Dr. Majima, member of the Tokyo Municipal Assembly, has been sent as a Japanese delegate to the international birth control union meeting, which will be held at Zurich, September 1. He left Yokohama, July 31, on the *Empress of Russia.*

The Most Disastrous Diseases

Mr. Y. Nakagawa, of the social bureau in the home department, stated in a lecture before the Research Society for Industrial Health that tuberculosis, venereal diseases and trachoma are the three most disastrous diseases in our country. They are especially of great consequence to workmen and laborers in the factories and mines. Though the regulations for the prevention of tuberculosis and trachoma were published by the government years ago and the antivenereal disease regulations were put in force three years ago, many workers and miners are still suffering from these diseases, which claim many victims year after year. According to figures published by the statistics bureau, 44,033 factories and workshops and 1,144,716 workers were protected by government health insurance in April, 1927, and 40 per cent of them were male. This year 3,321,234 insured have been treated by insurance physicians; 18,624 were inpatients. Tuberculosis cases numbered 628, which is 3.66 per cent of the insured inpatients and 60.35 per cent of the three national disease cases. Venereal disease cases numbered 270, which is 1.45 per cent of the insured inpatients and 23.90 per cent of the three national disease cases. Trachoma cases numbered 178, which is 0.96 per cent of the insured inpatients and 15.75 per cent of the three national disease cases.

Dr. Arima to Lecture Abroad

Dr. Arima, chief of the Arima Sanatorium in Osaka, has been invited to lecture before the Natural Science Society and the general medical meeting at Königsberg University, September 6 to 11. His subject will be "Special Treatment for Tuberculosis and My Investigation." He will also lecture in Moscow on his way to Germany, and after the meeting will make a two months' trip in Europe.

BERLIN

(From Our Regular Correspondent)

Sept. 15, 1930.

Progress of the Lübeck Investigation

Following the declaration of July 8, the federal ministry of the interior, under date of September 10, has published the following statement with regard to the progress that is being made in the investigation of the causes and conditions that led to the death from tuberculosis of more than sixty infants, in Lübeck, who had been inoculated with the B C G vaccine against tuberculosis:

The scientific investigations that have been carried on in the bureau of the federal health service, by Prof. Dr. Ludwig Lange, have produced these results:

1. The epidemiologic course of the cases of morbidity and the fatal cases shows marked periodic fluctuations, which bring out the fact that the vaccine materials that were prepared and administered at different times had a varying pathologic action. In contrast with certain periods with comparatively high morbidity and high mortality, there are others with a slight morbidity and with an absence of mortality, up to the present time.

2. The culture which was sent to Lübeck by the Pasteur Institute, which was cultivated further, after its arrival, on fluid mediums, and which was not used for the preparation of vaccine materials, has been found, on investigation, to be a pure B C G strain, without virulence for guinea-pigs.

3. Of the remaining B C G cultures from Lübeck, which were available for the government investigation, the oldest cultures (prepared in Lübeck, the middle of March, 1930) belonged to an inoculation period in which only a comparatively small percentage of the children were taken ill and none died from tuberculosis. The younger cultures, grown in the second half of April, 1930, had not been used for the preparation of vaccine materials. They were, however, included in the investigation. From the results of animal experiments, all these cultures have been freed of any suspicion of having consisted mainly or entirely of virulent tubercle bacilli. It appears likely that they were pure B C G cultures. The investigations are not, however, sufficiently advanced to state positively whether or not they contained *occasional* virulent tubercle bacilli.

4. In addition to these culture tubes, some remnants of four culture emulsions (vaccine material) used in the inoculation of children were brought into the investigation, two of which belong with certainty to vaccination periods presenting high morbidity and high mortality figures. The investigation of these vaccine materials, which the bureau of the federal health service did not receive until later, is still under way.

5. For the investigation there was another culture available that was derived from a guinea-pig which Professor Deycke had inoculated, March 6, with a supposedly pure emulsion of his B C G culture that he had cultivated in Lübeck on solid culture mediums. This culture, which was started, April 17,

showed, on examination at the bureau of the federal health service, high virulence for guinea-pigs but slight virulence for rabbits. Its behavior corresponds, therefore, to that of a culture of human tubercle bacilli.

Another guinea-pig, which was inoculated by Deycke, in Lübeck, April 17, with a different B C G emulsion, likewise supposed to be pure, had been brought alive to Berlin and, on being killed 109 days later, was found to be highly tuberculous. Researches on the exact behavior of this culture are still being carried on.

6. The portions of organs, which were taken at necropsy from the infants who had died from progressive tuberculosis and inoculated into guinea-pigs, produced in these animals progressive tuberculosis. Likewise, the cultures grown directly from such portions of organs show, according to the results of previous researches, high virulence for guinea-pigs but slight virulence for rabbits. The behavior of these cultures corresponds thus to that of a culture of human tubercle bacilli.

7. From the results of recent researches it is evident that the B C G culture furnished from Paris was unobjectionable in every respect and was not virulent.

To discover how the pathogenic and fatal action of so large a portion of the vaccine materials injected into the infants in Lübeck was brought about, researches are still in progress. The investigators are seeking to determine whether, through error or through the use of certain culture mediums, a contamination of the B C G culture with virulent tubercle bacilli occurred, or, on the other hand, whether or not a biologic metamorphosis may be suspected. In order to reach, as far as it is humanly possible, an unequivocal judgment in these matters, further comprehensive scientific researches must be carried out. The task proposed has been made more difficult, and its execution has been delayed, by the fact that the vaccine materials used in Lübeck for the inoculation of infants have been shown to be of a varying quality, for which reason they possessed a variable pathogenic action. This circumstance has made necessary a more comprehensive series of researches.

Health Services of Life Insurance Companies

For a number of years, many German life insurance companies have conducted a health department for the benefit of their policyholders. Persons insured for certain amounts have been granted, at certain intervals, special examinations and have been given medical advice as to the care of their health. This service has recently been extended by one large insurance organization. Persons who, for the preservation or lengthening of their life, are obliged to undergo a surgical operation are, on request, granted a special sum, without interest, to aid them in paying the costs of the operation. This aid, which takes the form of a non-interest-bearing prepayment of a portion of the sum for which the person is insured, is considerably higher than the regular loan value of the policy, for which interest is charged if a loan is made.

Rights of Physicians in the Choice of a Residence

Differences and misunderstandings constantly arise owing to the fact that one physician endeavors to take an apartment in a building in which another colleague resides. Consequently, the executive committee of the Gross-Berliner Aerztebund has published the following decision:

> A physician may not be allowed to take up his residence in an apartment building in which another physician having the same specialty already resides, without first securing the consent of that physician. On the other hand, it is not permissible that a physician shall enter into a contract with a house-owner, whereby the house-owner agrees to rent to no other physician a dwelling, for the practice of medicine, which is located within the same block. However, if an agreement of such a nature is made in which the area involved is that of an ordinary Berlin apartment building, even though it is, in a way, subdivided, or, for given reasons, actually forms two houses, it shall not be called into question.

Marriages

Charles Lee Quaintance, Queens Village, N. Y., to Miss Elizabeth Mary Coffey of New York, in August.

William H. Schowengerdt, Champaign, Ill., to Miss Minnie Berg of Bisbee, N. D., August 26.

William Robert Whiteford, Lieut., U. S. Navy, to Miss Mary Belle Harrison, August 27.

Ben Hamilton Nicholson, Nashville, Tenn., to Miss Winifred Tucker, September 2.

Kirby A. Martin, New York, to Miss Edna Peters, August 30.

Deaths

Emory Graham Alexander ⊕ Philadelphia; Jefferson Medical College of Philadelphia, 1904; member of the American Surgical Association and the American College of Surgeons; assistant professor of surgery, University of Pennsylvania School of Medicine; served during the World War; on the staffs of the University, Abington (Pa.) Memorial and the Episcopal hospitals; aged 50; died, August 29, when he severed his jugular vein with a pocket knife.

Asa Barnes Davis ⊕ New York; Medical Department of Columbia College, New York, 1889; member of the American College of Surgeons; member and past president of the American Association of Obstetricians, Gynecologists and Abdominal Surgeons; since 1918 chief surgeon of the Lying-In Hospital; aged 69; died, August 13, in St. Luke's Hospital, of angina pectoris.

Charles Moir ⊕ Louisville, Ky.; University of Louisville School of Medicine, 1898; at one time professor of pediatrics, Kentucky School of Medicine; formerly on the staffs of the Louisville City Hospital, St. Anthony's Hospital and the Kentucky School of Medicine Hospital; aged 66; died, July 8, in Lakeland, of endocarditis.

Oscar R. Tomlinson ⊕ Tate Springs, Tenn.; Tennessee Medical College, Knoxville, 1892; Bellevue Hospital Medical College, New York, 1894; past president of the Hamblen County Medical Society; aged 60; died, August 27, in a hospital at Fort Sanders, of complications, following an operation for appendicitis.

Joseph Tait Smith, Princeton, N. J.; University of Maryland School of Medicine, Baltimore, 1872; member of the Medical and Chirurgical Faculty of Medicine; formerly associate professor of hygiene and clinical medicine at his alma mater; aged 80; died, in May, in Cleveland, of carcinoma of the prostate.

Effie Alberta Read, Washington, D. C.; George Washington University Medical School, Washington, 1912; assistant chief of the micro-analytical laboratory of the bureau of chemistry, department of agriculture; aged 57; died, September 1, of carcinoma of the ovary with general metastases.

John Howard Thompson, Mescalero, N. M.; Medical College of Ohio, Cincinnati, 1881; past president of the El Paso (Texas) County Medical Society; formerly member of the school board in El Paso, Texas; aged 79; died, May 14, in El Paso, Texas, of cardiac infarction.

Orlando L. Sutherland, La Porte, Ind.; University of Michigan Homeopathic Medical School, Ann Arbor, 1891; member of the Indiana State Medical Association; aged 70; died, August 10, in the Presbyterian Hospital, Chicago, of pneumonia, following an operation.

J. Arthur Mullins, Marlow, Okla.; University of Oklahoma School of Medicine, Oklahoma City, 1911; member of the Oklahoma State Medical Association; aged 50; was found dead, August 11, of burns received when the gasoline tank in his automobile exploded.

Louis Brinton Yerger, Wilmington, Del.; Hahnemann Medical College and Hospital of Philadelphia, 1914; member of the Medical Society of Delaware; aged 40; on the staff of the Homeopathic Hospital, where he died, in August, of carcinoma of the cecum.

Wade Hampton Brannon, Anniston, Ala.; Birmingham Medical College, 1910; member of the Medical Association of the State of Alabama; past president of the Calhoun County Medical Society; on the staff of the Grover Hospital; aged 43; died, August 17.

Hiram Byrd ⊕ Detroit; University of Georgia Medical Department, Augusta, 1902; director of the department of hygiene, University of Mississippi, 1919-1920, and at the University of Alabama, 1920-1922; aged 55; died, July 20, of angina pectoris.

Claude L. Rawlings ⊕ New Harmony, Ind.; Washington University School of Medicine, St. Louis, 1903; secretary and past president of the Posey County Medical Society; aged 50; died, August 27, in the Walker Hospital, Evansville, of acute pyelonephritis.

Jeremiah Francis Brennan, Boston; Tufts College Medical School, Boston, 1923; member of the Massachusetts Medical Society; on the staff of St. Elizabeth's Hospital, where he died, August 27, aged 37, of bronchopneumonia and cardiorenal disease.

Harold J. Chapman ⊕ Speed, Kan.; Wisconsin Eclectic Medical School, Milwaukee, 1896; aged 62; died, June 30, in the Presbyterian Hospital, Chicago, of peritonitis, following operation for obstruction of the duodenum and gallstones.

Roy Logan Stackpole, Pittsburgh; Western Reserve University School of Medicine, Cleveland, 1901; past president of the Butler (Pa.) County Medical Society; aged 53; died, August 21, of lung abscess and mediastinal tumor.

William Franklin Matson, Denver; State University of Iowa College of Medicine, Iowa City, 1896; member of the *Colorado State Medical Society; aged 66; died, August 11, in* Victoria, B. C., Canada, of heart disease.

J. Ensor Hutcheson ⊕ Rockville Center, N. Y.; Bellevue Hospital Medical College, New York, 1890; past president of the Medical Society of the County of Nassau; aged 61; died, August 16, of chronic endocarditis.

Alexander Aisman ⊕ Brooklyn; University and Bellevue Hospital Medical College, New York, 1912; on the staff of the Jewish Hospital; aged 39; died, August 16, of chronic nephritis and myocarditis.

Benjamin Franklin Pearce, Lancaster, Pa.; Medical College of Virginia, Richmond, 1929; intern, St. Joseph's Hospital; aged 30; hanged himself, August 12, in the State Hospital, Raleigh, N. C.

John Atkinson Hunnicutt, Athens, Ga.; Atlanta Medical College, 1866; Civil War veteran; formerly mayor, president of the bank, and member of the school board; aged 92; died, August 10.

William Cheney Watts, Drew, Miss.; University of the South Medical Department, Sewanee, Tenn., 1896; aged 55; died, July 27, in Greenwood, of splenomegaly following undulant fever.

Herman S. Spear, North Anson, Maine; Dartmouth Medical School, Hanover, N. H., 1897; member of the Maine Medical Association; aged 61; died, May 22, of coronary occlusion.

Washington Irving Goewey, Albany, N. Y.; Albany Medical College, 1892; aged 72; died, July 31, in the Glens Falls (N. Y.) Hospital, of injuries received in an automobile accident.

Edward C. Ayres, Lorimor, Iowa; State University of Iowa College of Medicine, 1894; past president of the Union County Medical Society; aged 64; died, July 13, of angina pectoris.

Martin L. Oilar, Russiaville, Ind.; Medical College of Ohio, Cincinnati, 1875; aged 78; died, August 21, in the Johns Hopkins Hospital, Baltimore, of hemorrhage due to gastric ulcer.

William N. Wardlaw, Childress, Texas; Fort Worth School of Medicine, 1895; member of the State Medical Association of Texas; aged 60; died, May 27, of acute nephritis.

Charles M. Long, Osakis, Minn.; Rush Medical College, Chicago, 1878; aged 81; died, August 3, in a hospital at Alexandria, of carcinoma of the cecum and intestinal obstruction.

James C. Welch, Salem, Mo.; Medical College of Ohio, Cincinnati, 1889; member of the Missouri State Medical Association; aged 69; died, May 30, of cerebral hemorrhage.

Walter Arthur Monnich, Minneapolis; Baltimore Medical College, 1910; served during the World War; aged 46; died, August 28, in Prescott, Ariz., of pulmonary tuberculosis.

Guilford Sims Wright, Cowan, Tenn.; Vanderbilt University School of Medicine, Nashville, Tenn., 1895; aged 56; died, August 12, in Sewanee, of carcinoma of the lung.

Newton Bolivar Haney, Fort Worth, Texas; Vanderbilt University School of Medicine, Nashville, Tenn., 1882; aged 76; died, July 24, of myocarditis and arteriosclerosis.

Eduard Sylvester Smith, Jr. ⊕ New York; University of Vermont College of Medicine, Burlington, 1916; served during the World War; aged 40; died, July 6.

Frederick Raymond Devine ⊕ Riverside, R. I.; University of Maryland School of Medicine, Baltimore, 1913; aged 38; died suddenly, August 15, of heart disease.

Joseph Eloi Fontaine, Hull, Que., Canada; School of Medicine and Surgery of Montreal, 1891; formerly mayor of Hull; aged 64; died, June 11, of myocarditis.

John A. Weamer ⊕ Tarentum, Pa.; Baltimore Medical College, 1896; on the staff of the Allegheny Valley Hospital; aged 61; died, August 31, of lung abscess.

Joseph Edward Quinn, New York; Fordham University School of Medicine, New York, 1921; surgeon, U. S. Public Health Service; aged 32; died, July 25.

James McMahon, Texarkana, Ark.; Queen's University Faculty of Medicine, Kingston, Ont., Canada, 1873; aged 86; died, August 3, of cerebral hemorrhage.

George Ernest Webber ⊕ Morland, Kan.; Medico-Chirurgical College of Kansas City, 1904; aged 57; was killed, August 12, when his car hit a culvert.

David Michael Flannery, Brooklyn; Medical Department of the University of the City of New York, 1880; aged 81; died, August 20, of arteriosclerosis.

Lucius B. Bates, St. Matthews, S. C.; University of South Carolina Medical Department, Columbia, 1868; Confederate veteran; aged 83; died, August 14.

Le Roy Dibble, Kansas City, Mo.; Bellevue Hospital Medical College, New York, 1871; Civil War veteran; aged 86; died, August 6, of nephritis.

William Merrill Hutchinson, Pompton Plains, N. J.; Long Island College Hospital, Brooklyn, 1881; aged 70; died, June 8, of chronic myocarditis.

Joseph Davis Todd, Adrian, Mo.; College of Physicians and Surgeons, Keokuk, Iowa, 1869; Civil War veteran; aged 86; died, May 24, of senility.

Eugene Lee McCurdy, Stone Mountain, Ga.; Emory University School of Medicine, Atlanta, 1924; aged 31; died, July 27, of pulmonary tuberculosis.

Samuel M. Stedman, Versailles, Ky.; University of Louisville School of Medicine, 1891; aged 62; died, August 7, in the Woodford Memorial Hospital.

Newton Bruce Marsh, Falkner, Miss. (licensed, Mississippi, 1882); aged 69; died, August 26, of heart disease.

John Calvin Smith ⊕ Catoosa, Okla.; Baltimore Medical College, 1902; aged 54; died, July 20.

Bureau of Investigation

THE STROOPAL FRAUD

Another "Cancer Cure" Denied the Use of the Mails

For many years a nostrum known as Stroopal has been sold on both sides of the Atlantic as a cure for cancer. The stuff apparently originated in Germany. For some years it was exploited from London, and the fraud was exposed by London *Truth* nearly twenty years ago. In the "Cautionary List" which that militant weekly issued annually at that time, the following brief paragraph appeared:

> "Stroopal.—A cancer-cure purveyed by a Mr. W. Faupel, of Windsor-lodge, Hartfield-road, Wimbledon. The cure is made in Germany by a 'Professor' Stroop and consists of three powders to be taken at monthly intervals when the moon is new. Its advertisement has been stopped in Germany under the law which forbids the advertisement of secret remedies."

According to Gehe's Codex (January, 1913, page 99) Stroopal is composed of the powdered leaves of *Teucrium Scordium,* otherwise known as water germander or wood garlic.

For at least seventeen years, and probably longer, Stroopal has been exploited in a small way from Chicago. At first it seems to have been sold by a rather crude concern known variously as the "Institute of Regeneration" and "Institute of Reform," which operated from various addresses in Chicago. This concern, which seems to have been operated by one E. P. Handl, addressed itself especially to the German-American element, a large part of the advertising matter being printed in German script. Part of the "come-on" literature consisted in photographic reproductions of so-called Diplomas of Merit from European expositions, each showing that such a "Diploma" was issued to Mr. A. Stroop, the originator of Stroopal. In addition, there were reproduced photographically the official trade-mark specifications issued to Ernst Handl from the United States Patent Office for certain nostrums.

More recently Stroopal seems to have been advertised under the name of the Stroopal Company, 2101 Belmont Avenue, Chicago. This is the address of a small butcher shop.

The postal authorities on August 13, issued a fraud order against the Stroopal Company and notified the Chicago postmaster to return all letters addressed to the Stroopal Company to the original senders, after having stamped on the letters "Fraudulent."

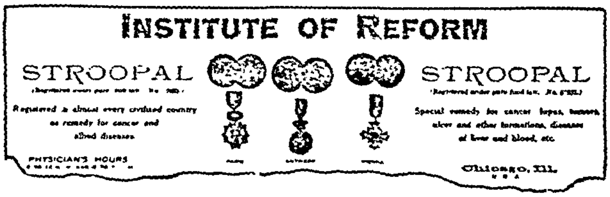
The memorandum of the Solicitor of the Post Office Department to the Postmaster-General, recommending the issuance of a fraud order, states that after the postal authorities had notified the Stroopal Company at Chicago and its agents, one John Altbaumer at Centralia, Okla., and a Mrs. E. Boeding at Seneca, Kansas, to show cause why a fraud order should not be issued against them, no appearance was made either in person or by attorney on the date set for the hearing. A week later, according to the memorandum, John A. Nash, a Chicago attorney, appeared in Washington and presented informally a written answer denying the charges. Readers of this department of The Journal may remember that the reports that have been published of medical mail-order frauds have recorded the appearance, as attorney, of John A. Nash of Chicago in other cases: The "Lavex" "catarrh cure" fraud of Kansas City, Mo.; the aphrodisiac fraud of Jean Jacques Laboratories of Chicago; the "lost manhood" fraud of A. T. Hay of Chicago; the Burgess and Johnson frauds of Kansas City, Mo. The Solicitor's memorandum states in part:

> "The Stroopal Company is a trade name used by one Alphonse Faupel, John Altbaumer and Mrs. E. Boeding in the sale through the mails of a product called Stroopal. It is claimed by the promoters of this product that it was 'born' 150 years ago in the laboratories of a great physician of Northern Westphalia. This physician is alleged to have been a close friend of the Stroop family and to have given to its members the secret formula for his preparation, in return for performance of an 'unusual service.' The product is manufactured in Germany and is forwarded to Mr. Faupel at Chicago, where it is dispensed by him from a meat market operated by his brother. Mr. Altbaumer and Mrs. Boeding are agents.
>
> "The evidence shows that Stroopal is sold through the mails upon representations to the effect that, when used as directed, it will cure cancer, tumors, goiter and all internal and external swellings, blood diseases, piles, boils, ulcers, lupus, eruptions, stomach, liver, kidney and gallstone ailments, mastitis, delayed and painful menstruation; that it restores the tissues; that it succeeds in seemingly hopeless cases when all else, even the surgeon's knife has failed, and that it is an effective preventive of disease."

Business was obtained by means of circulars and form-letters, as well as advertising leaflets and other material. The memorandum then continues:

> "The evidence shows that Stroopal is composed of the powdered leaves of *Teucrium Scordium,* otherwise known as water germander or wood garlic. A so-called full course of Stroopal consists of three 'principal' powders to be taken one a month. In addition, 'intermediate' powders to be taken one a week by persons on whom the disease or condition involved has gained a 'strong hold' are also purveyed. The literature directs that the 'principal powders' be taken at 'new moon' and the supplemental or 'intermediate powders' at 'full moon.' According to these directions, 'urgent' cases permit taking of 'intermediate' powders on 'any other days' but 'best always at the first and last quarter-face of the moon.' The price of the so-called full course is $6. Intermediate powders are sold at $1 each, but their sale is limited to purchasers of the full course."

The Solicitor in his memorandum to the Postmaster General stated that, according to scientific medicine, the crude drug of which Stroopal is composed, while once popularly used for cancer and other serious diseases, is now entirely obsolete, except as a means of discouraging moths. He pointed out, further, that the use of Stroopal in cases of cancer was worse than worthless, because of the delay in instituting scientific treatment of the condition.



INSTITUTE OF REFORM

STROOPAL

Registered in almost every civilized country as remedy for cancer and allied diseases.

PHYSICIAN'S HOURS

STROOPAL

Special remedy for cancer lupus, tumors, ulcer and other formations, diseases of liver and blood, etc.

Chicago, Ill.

The Solicitor also calls attention to the fact that some of the advertising matter for Stroopal purported to reproduce pictures of medals and other declarations said to have been awarded at exhibitions held in various European cities, including Antwerp, Belgium, and Paris. The Solicitor states that investigation by representatives of the United States government in these European cities shows that no exhibitions of the character mentioned were ever held in these places. In this connection, it is worth reminding our readers that this department of The Journal, some years ago (March 4, 1914), published an article describing some of these fake Grand Prix, diplomas and gold medals and how they were obtained. This matter is reprinted in the pamphlet, "Some Quasi-Medical Institutions," prepared and issued by the Bureau of Investigation.

The memorandum then closes with these paragraphs:

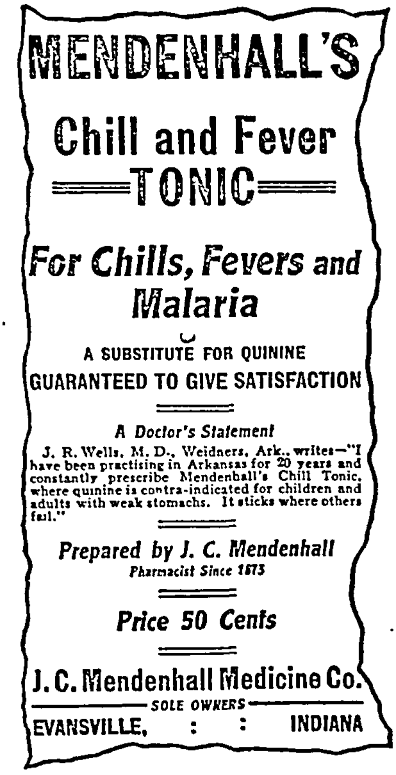
> "The history of Stroopal in America has been turbulent. Barred from entry as dangerous to the health of the people of the United States, it was for a time smuggled into the country as 'metal cleaning powder.' Its American vendors have, moreover, on at least one occasion, been driven from business by local authorities and a number of spurious medals and diplomas confiscated. Approximately 40 pieces of mail are being received daily at Chicago, Ill., addressed to the Stroopal Company.
>
> "John Altbaumer at Centralia, Okla., and Mrs. E. Boeding at Seneca, Kansas, have been permitted to abandon this scheme by filing affidavits to that effect in this office, thus obviating the necessity of the issuance, at this time, of a fraud order against their personal names.
>
> "The evidence shows that this is a scheme for obtaining money through the mails by means of false and fraudulent pretenses, representations and promises, and I so find.
>
> "I, therefore, recommend that a fraud order be issued against the Stroopal Company and its officers and agents as such, at Chicago, Ill."

MORE MISBRANDED NOSTRUMS

Abstracts of Notices of Judgment Issued by the Food and Drug Administration of the United States Department of Agriculture

Schieffelin Cold and Grippe Tablets.—Schieffelin and Company, New York City, shipped in January, 1929, into New Jersey a quantity of Schieffelin's Cold and Grippe Tablets that were declared misbranded. The tablets were found on analysis to contain acetanilide, cinchona alkaloids, red pepper, camphor, aloin and extracts of plant drugs, including a laxative drug. The claim that it was a remedy for influenza was declared false and fraudulent and in July, 1929, judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed.—[*Notice of Judgment 16583; issued February, 1930.*]

Mendenhall's Chill and Fever Tonic.—The J. C. Mendenhall Medicine Company, Evansville, Ind., shipped in January, 1929, to St. Louis, Mo., a quantity of Mendenhall's Chill and Fever Tonic that was declared adulterated and misbranded. Analysis showed the stuff to consist essentially of quinidine sulphate (6.32 grains to the fluid ounce), a laxative plant drug extractive, glycerine, alcohol, sugar, water and a trace of benzoate of soda. Adulteration was charged in that it was claimed on the trade package that it contained no dangerous drug when, as a matter of fact, each fluid ounce contained the equivalent of several grains of quinine; it was declared misbranded because the claims that it was a cure for influenza, general debility, loss of appetite, jaundice, biliousness, etc., were false and fraudulent. In June, 1929, judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed.—[*Notice of Judgment 16546; issued March, 1930.*]



MENDENHALL'S

Chill and Fever

TONIC

For Chills, Fevers and Malaria

A SUBSTITUTE FOR QUININE

GUARANTEED TO GIVE SATISFACTION

A Doctor's Statement

J. R. Wells, M. D., Weidners, Ark., writes—"I have been practising in Arkansas for 20 years and constantly prescribe Mendenhall's Chill Tonic, where quinine is contra-indicated for children and adults with weak stomachs. It sticks where others fail."

Goodwin's Cold Breakers.—The Senoret Chemical Company of St. Louis, Mo., shipped to Wheeling, W. Va., in December, 1928, a quantity of Goodwin's Cold Breakers that were declared misbranded. The tablets were found on analysis to contain acetanilide, aloin, strychnine and a laxative plant drug. The claim that it was a remedy for influenza was declared false and fraudulent. In May, 1929, judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed.—[*Notice of Judgment 16590; issued February, 1930.*]

Sternox.—The Sterno Corporation, New York City, shipped to Connecticut in January, 1929, a quantity of Sternox which was declared misbranded. The federal chemists reported that Sternox was essentially petrolatum with small amounts of camphor, menthol, turpentine, thyme and eucalyptus oils. The claim that it was a remedy for coughs, influenza, croup, etc., was declared false and fraudulent and in June, 1929, judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed.—[*Notice of Judgment 16550; issued March, 1930.*]

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted on request.

"THE THIN CHILD AND CALCIUM"

To the Editor:—The article in *Good Housekeeping Magazine* for June, 1930, "The Thin Child and Calcium," by Dr. Josephine H. Kenyon, has caused not a few of my patients to call up with reference to the treatment. May I be advised if sufficient scientific investigation has been done to carry out the treatment as outlined without control laboratory blood calcium findings. This type of child, usually the only child of a neuropathic parent, constitutes about 30 per cent of my office practice, but I hesitate to employ such treatment as outlined without blood calcium determinations for fear of a hypercalcemia.

Gordon Chown, M.D., Winnipeg, Manit.

Answer.—The article on "The Thin Child and Calcium" deserves some comment. The author assumes that severe forms of underfunction of the parathyroid gland are an underlying factor in such habits as blinking, twitching, head nodding, bed wetting, and some cases of temper tantrums. In order to prove this statement it would be necessary to demonstrate a dysfunction of the parathyroid gland. The only possible means of showing parathyroid gland deficiency consists in finding a lowered serum calcium or the signs of manifest or latent tetany, such as increased nervous irritability on the application of a galvanic current (cathodal opening contraction less than 5 milliamperes); Erb's sign or the presence of the facial phenomenon, Chvostek's sign in which active muscular twitching occurs on mechanical stimulation of the muscles supplied by the facial nerve, or Trousseau's sign, which is characterized by a carpal contracture if a constriction is applied above the elbow.

The writer, Dr. Kenyon, who is advising "Mothers of the Health and Happiness Club," does not inform us that she has taken pains to establish a correct diagnosis of parathyroid deficiency and consequently one may question whether her assumption is correct. The diagnosis is certainly not a simple one and cannot be readily made.

The author continues describing an undernourished child who looks old for his years and holds his muscles tensely. He is overactive, sleeps little, and finds it hard to concentrate. The author states that these are sad looking children; they worry; they may become easily angry; they lack in physical endurance. The author believes that these children respond splendidly to calcium and parathyroid gland medication. This is doubtful. As the writer of the question says, these neuropathic children form a considerable part of every doctor's office practice. The biochemistry of this group of children is little understood. May it not be assumed that the gastro-intestinal symptoms, attacks of mucous diarrhea, and distressing or cyclic vomiting are due to the effect of an unstable nervous system on metabolic processes?

It is not uncommon in this group of children to encounter, during the emotional outbursts, acidosis, diminution in the alkali reserve in the blood, and a transient hypoglycemia. As a rule, contrary to what is found in tentany, these children are relaxed and hypotonic. It would be difficult or impossible to analyze the pathogenesis of these emotional states. There are undoubtedly hereditary, environmental and organic factors that are not readily discernible. But to say that they are almost invariably due to hypocalcemia or hypofunction of the parathyroid gland is going almost too far.

The author also advises among other things viosterol. It would seem that the public is being ill advised about the promiscuous use of this remedy. Physicians themselves have still to be educated in its use and dosage. Reports are just beginning to come in which seem to indicate that the dangers of hypermineralization have still to be ascertained.

Dr. Kenyon closes by saying that it is wonderful to see the thin child quiet down, become less combative, put on weight and really sleep after the calcium-parathyroid-viosterol treatment among several other things that are advised.

Medical authors who address themselves to the public should exercise considerable caution in giving advice about treatment. It would be well, too, if they based their advice and deductions on well founded clinical and scientific knowledge.

If the public is to be educated in medical matters, and it is right that it should be, the information should be useful, exact and harmless. Conditions and indications of treatment and the selection and dosage of remedies should invariably be referred to the family physician.

Alfred F. Hess in his book "Rickets, Osteomalacia and Tetany" (Lea & Febiger, 1929, pp. 399-400) has the following to say about the use of parathyroid extract: Since the parathyroid extract has been used in various clinics for two to three years it has not been found to be perfectly satisfactory. Clinical results are irregular and the rise in calcium variable. Some infants react with marked depression associated with pallor, vomiting and mild diarrhea, symptoms that may give cause for *alarm*. The extract does not act as a curative but is purely symptomatic, increasing the calcium in the blood by drawing on the calcium reserve of the bone.

McCOLLUM BALANCED DRY DIET FOR LABORATORY ALBINO RAT

To the Editor:—Will you kindly advise me concerning the exact composition of the McCollum balanced dry diet for the laboratory albino rat.

Harry M. Miller, Jr., Ph.D., Friday Harbor, Wash.

Answer.—Presumably the following ration is referred to (McCollum, E. V.: *Bull. Johns Hopkins Hosp.* **33**:202, 1902):

	Per Cent
Wheat	30
Maize	30
Rolled oats	30
Linseed meal	10

Whole milk is supplied ad libitum and twice a week fresh greens or carrots.

The ration recommended by Steenbock (*Science* **58**:449, 1923) is as follows:

	Per Cent
Yellow corn meal	76.0
Linseed meal	16.0
Commercial casein	5.0
Ground alfalfa	2.0
Sodium chloride	0.5
Calcium carbonate	0.5

Fresh whole milk is supplied ad libitum.

Sherman has employed a mixture of ground whole wheat, 3 parts; whole milk powder, 1 part, together with common salt equivalent to one per cent of the mixture. This has been modified to meet the requirements of lactation better (Smith, A. H., and Anderson, W. E.: *Science* **70**:98, 1929) as follows:

	Per Cent
Ground whole wheat	65.8
Whole milk powder	32.8
Calcium carbonate	0.7
Sodium chloride	0.7

Lettuce is also supplied daily; and during the period of lactation the females receive dried yeast three times a week.

H. M. Evans (*Am. J. Physiol.* **85**:154 [May] 1928) has recommended the following ration:

	Per Cent
Whole wheat	67.5
Casein	15.0
Whole milk powder	10.0
Sodium chloride	1.0
Calcium carbonate	1.5
Butter fat	5.0
Fresh lettuce	

All of these diets are discussed in the monograph of A. H. Smith and L. B. Mendel entitled "Praktisches Verfahren bei *Ernährungsversuchen*," *in* Abderhalden's Handbuch der biologischen Arbeitsmethoden, 1930, section IV, part 13, pp. 117-172.

BLOOD IN FETUS—DEATH OF FETUS AFTER INTERFERENCE WITH CIRCULATION

To the Editor:—Will you kindly answer the following questions or give references where the information might be found: 1. What is the average total volume of blood in a fetus at term, including the cord and placenta? 2. What percentage of the total is in the fetus? In the cord? In the placenta? 3. How long after compression of the cord will a six month fetus in utero live? A fetus at or near term? Please omit name.

M.D., Texas.

Answer.—1. As far as is known, no one has determined the amount of blood that is to be found in the fetus, the umbilical cord and the placenta at the same time. This question would be difficult to settle because each of the three components may vary considerably and the amount of blood would depend on the variations present. Thus, as far as the fetus is concerned, it is known that the the amount of blood varies with the size of the fetus and also with the time the cord is ligated. If a delay of a few minutes is made following the birth of the child before the cord is ligated, the child will obtain an additional 40 to 60 cc. of blood from the placenta. In general, the volume of blood found in a new-born baby is approximately one eleventh of the body weight. Since the average weight of new-born babies is about 3,100 Gm., the average amount of blood is about 280 Gm.; but factors other than body weight undoubtedly play a part in the volume of blood present.

2. Likewise the amount of blood to be found in the umbilical cord will vary with the length of the cord, the number of twists it has, the caliber of the blood vessels, and the number of blood vessels. The amount of blood in the placenta varies with the size of the organ, the richness of the villi, the size and number of infarcts, the amount of calcification and other factors.

3. It is difficult to say how long a 6 months fetus in utero can live after compression of the cord because clinically such an occurrence is extremely rare. Most likely the length of time is less than that for a full-term child. The latter may live as *long as twenty minutes after compression of the cord*, although this is unusual. Most babies do not survive more than ten to twelve minutes after the circulation in the cord is completely obliterated.

INJECTION METHOD FOR VARICOSE VEINS—SALT SOLUTION FOR CEREBRAL DEHYDRATION—MALARIAL TREATMENT OF DEMENTIA PARALYTICA

To the Editor:—1. When a solution of sodium chloride is used in the injection treatment of varicose veins, what strength solution is to be used? 2. What is the percentage of salt used in sodium chloride solution, when hypertonic salt solution is given intravenously, for cerebral edema or increased intracranial tension? 3. Please give me enough of the details of the treatment of syphilitic dementia paralytica by infection with malaria to enable me to treat a case by this method. Kindly omit name.

M.D., Montana.

Answer.—1. McLatchie (The Treatment of Varicose Veins by Intravenous Injections, published by the Macmillan Company, 60 Fifth Avenue, New York, in 1929) says that sodium chloride is usually employed in a 15 to 20 per cent solution. The quantity injected at one sitting is from 5 to 10 cc., but larger amounts can be used. For patients of an advanced age a stronger solution up to 25 per cent may be required.

Douthwaite (The Injection Treatment of Varicose Veins, published by Lewis and Company, Ltd., 28 Gower Place, London, W. C. 1, in 1928) says that a 20 per cent solution of sodium chloride injected in quantities of from 4 to 10 cc. gives, *not infrequently*, good results but is not certain in its effects. Cramplike pains are produced immediately after injection, similar in nature to those due to salicylate.

Kern and Angle (The Journal, Aug. 24, 1929) say that there are five solutions being used rather extensively in Europe and in this country, namely, sodium chloride, 15 to 30 per cent; sodium salicylate, 20 to 60 per cent; dextrose, 50 per cent; a mixture of sodium chloride, 10 per cent and sodium salicylate 25 per cent; and quinine and urea (0.5 Gm. of quinine and 0.25 Gm. of ethylurethane in 2 cc. of water). There are valid objections to all of these solutions. In the case of sodium chloride and sodium salicylate, they say, the cramp following the injection is severe and there is at times a very marked perivenitis after injection, with infiltration, redness and tenderness of the skin and subcutaneous tissue surrounding the vein.

The use of sodium chloride for this purpose is further discussed in an article in The Journal, March 9, 1929, by de Takáts. It might be well to call attention also to a Current Comment in The Journal, May 14, 1927, page 1571, concerning a case reported by Lomholt. This patient had been given *five injections of 5 cc. each of 20 per cent sodium chloride solution*. The saphenous vein became thrombotic up to the fossa ovalis and in two weeks the symptoms of pulmonary embolism developed. The patient overcame the attacks, but about one month after the injection treatment he died suddenly of embolism of the pulmonary artery. Lomholt (at that time) said that only one similar case is reported in the literature and in that case the embolism was traced to infected hemorrhoids.

2. This question was answered in Queries and Minor Notes (The Journal, May 5, 1927) under the heading "Hypertonic Salt Solution for Cerebral Dehydration." Fay (The Journal, May 19, 1923) tabulated fifteen cases in which hypertonic sodium chloride solution was injected. The proportions used in most of these cases were 15 per cent; in one, 18 per cent, and in the remainder, 35 per cent.

Peet (Reduction of Increased Intracranial Pressure by Intravenous Administration of Glucose and Hypertonic Ringer's Solution, The Journal, June 27, 1925) says that the rapid reduction of intracranial tension in acute intracranial traumas unassociated with shock is best accomplished by the intravenous administration of hypertonic Ringer's solution. Dextrose may be given later to maintain the lowered intracranial pressure. Hypertonic dextrose solution administered intravenously is indicated when acute intracranial pressure is associated with shock or hemorrhage, and in the less acute cases when complicated by dehydration, nausea and vomiting. Dextrose has the following advantages over any of the salt solutions: prolonged action, no terminal rise in pressure, nontoxicity, nondehydration, increased blood volume in shock, and the control of acidosis.

The intravenous introduction of all hypertonic solutions must be made slowly. Any sudden change in the pulse is a warning to stop the flow of the solution for a moment, and further introductions must be at a slower rate. The subject is further discussed by Brain in the *British Medical Journal*, Jan. 21, 1928.

3. This treatment should not be undertaken by one who has not had considerable experience with the method. In the first place the treatment is being given more and more to a selected group of patients, as not all patients do well and there is some times considerable danger involved. The correspondent might read an article in The Journal, Feb. 21, 1925, by Bunker and Kirby, entitled "Treatment of General Paralysis by Inoculation with Malaria," and articles in the *Archives of Neurology and Psychiatry*, August, 1926, and October, 1929, by McIntyre and McIntyre and by DeAsis, respectively.

TULAREMIA AND WIDAL TEST

To the Editor:—A patient developed a sore on a finger, followed in a few days by adenopathy at the elbow and in the axilla. This was accompanied by chills and fever. After about two weeks the adenopathy disappeared but the fever continued, being about 100 to 104 F., usually about 102. At the end of two weeks a Widal test was returned positive, making the diagnosis of typhoid apparently conclusive. It occurs to me, however, that tularemia could be present in this case. Could it be that the presence of the tularemia could give a clumping of the typhoid bacteria and in that way a positive Widal when typhoid does not exist?

G. H. Parmenter, M.D., Beecher City, Ill.

Answer.—Francis and Evans and Simpson have reported that serums giving a positive agglutination reaction with *Bacterium tularense* do not show cross-agglutination with *B. typhosus, B. paratyphosus* A and *B. paratyphosus* B. Cross-agglutination of *Brucella abortus* and *Brucella melitensis* does occur in about 37 per cent of serums which give a positive reaction for tularemia. The history and the proportionately higher titer reached by anti-*tularense* agglutinins usually leave no doubt as to the proper interpretation of the serologic observations in the event of cross-agglutination of *Brucella* and *Bacterium tularense.* In view of the fact that anti-*tularense* agglutinins persist in the serum indefinitely, it would still be possible to test the serum of the patient for the presence of tularemia infection. It is not uncommon to obtain a positive Widal reaction in patients who have been previously inoculated with the single typhoid vaccine or the triple vaccine (*typhosus, paratyphosus* A and *paratyphosus* B). A positive Widal reaction may also be obtained from persons who have recovered from a previous typhoid infection. With the exception of the occasional cross-agglutination of *Bacterium tularense* and *Brucella,* the agglutination reaction for tularemia is highly specific.

VARIATIONS IN SOIL AND VITAMIN CONTENT OF FOODS

To the Editor:—Do variations of the chemical or other elements in a soil change the amount or nature of the vitamins in the foods produced in that soil? May I have the sources of this information? I have become much interested in the vitamins and the soils and foods in this country as so many of our children have early dental caries. An analysis of the soils here is shortly to be made that will possibly give some slight information on this point, but I am wondering how different soils, acid, and otherwise, would affect, if any, the vitamin contents of the foods. I have not yet come across any statement on that line.

Elwood L. Davis, M.D., Kijabe, East Africa.

Answer.—We are not aware of any evidences that the nature of the vitamins in plant products can be altered by either intentional or fortuitous changes in the agricultural conditions. It is by no means unlikely, however, that the content of characteristic vitamins in edible species of plants varies with soil and other environmental conditions. These affect the rate of growth, the proportions of leaf to stem, tubers and roots, and the character of the fruit, so that the amount of a given vitamin in a single plant or unit weight of edible portion may be varied in unmistakable degree. Green leaves are as a rule richer in vitamin A than are the unpigmented parts of the plant. Variations in the vitamin content of green and "pale" lettuce have been demonstrated repeatedly; for example, in the studies of Crist and Dye at the Michigan Agricultural College, East Lansing. The antiscorbutic potency (content of vitamin C) of some plants varies with the stage of growth, which in turn is modified by soil conditions. The subject is one that is at present engaging the attention of scientific investigators, notably in the agricultural experiment stations. It is rather early to draw broad generalizations. Information regarding existing published articles should be obtainable from the Bureau of Chemistry and Soils and the Bureau of Home Economics, U. S. Department of Agriculture, Washington, D. C.

The effect of the composition of soils on the products of plant growth that it yields is shown in connection with the mineral ingredients of the vegetation. In South Africa, where there is a shortage of phosphorus in the soils of some of the grazing lands, the vegetation reflects this deficiency. Cattle maintained on the grasses exhibit pica, or depraved appetite, leading them to eat bones or other sources of the much desired element wherever available. Osteophagia, or bone eating, in cattle is reported to occur in parts of the southwest United States.

Soil conditions are conspicuously responsible for variations in the iodine content of edible plant foods. This is a matter of considerable moment in relation to goiter prophylaxis. As a rule the iodine content of plants tends to decrease as one proceeds inland. This is true of the Middle West and the Great Lakes region. Researches undertaken by the state of South Carolina have indicated that edible crops raised inland in that region have an unexpectedly large iodine content. The potatoes of the Piedmont area are relatively rich in iodine in comparison with the tubers from most potato-producing states. This is presumably due to unique soil conditions related to the geology of the region; possibly in part to the extensive use of Chilean fertilizers that are comparatively rich in iodine. The problems thus presented are within the domain of human nutrition and deserve further study.

With respect to dental caries it is hazardous to venture dogmatic opinions at the present stage of knowledge. The progress of investigations has been recorded from time to time. Undue consumption of sugar and the development of acidophilic flora in the mouth; shortage of vitamin D; lack of vitamin C with development of latent scurvy; lack of adequate oral hygiene; these and other factors have been charged from time to time with responsibility for caries and also periodontal disorders. It is too early to venture any tenable hypothesis, though there can be little doubt that disordered nutrition may readily play a part in the gradual development of profound dental defects.

ANTITOXIN IN DIPHTHERIA

To the Editor:—In looking over my old files of The Journal, I find an editorial in the issue of Dec. 12, 1914, on the administration of antitoxin in diphtheria, an article which I had completely forgotten. This article states that it is useless to give to a child of 44 pounds more than 2,000 units in an ordinary case, and 10,000 units in a very severe case. Also to a person weighing 132 pounds, it is useless to give more than 6,000 units in an ordinary case, or more than 30,000 units in a very severe case. Can you tell me whether this dosage is still considered the maximum that should be given? If so, it will prevent me ever again giving 165,000 units.

J. R. Truscott, M.D., Binford, N. D.

Answer.—There are probably few, if any, physicians of large experience in treating diphtheria who would be satisfied to limit the dose of antitoxin in all cases to 30,000 units. In many hospitals in which late and neglected cases of diphtheria are common, a total of 100,000 units is not infrequently given with apparent benefit. In the Providence City Hospital from 1910 to 1928 the average dose of antitoxin given to diphtheria patients varied by years from 14,338 to 38,126 units, and in 1928 the average dose given to patients who recovered was 26,610 units. The important thing is to give at the earliest moment an adequate dose of antitoxin. If part or all of the antitoxin is introduced directly into a vein, the total may be somewhat reduced. An excess of antitoxin does no harm, but a deficiency may allow fatal injury from the disease.

QUINIDINE IN AURICULAR FIBRILLATION

To the Editor:—A woman, aged 63, has had attacks of paroxysmal auricular fibrillation for the past three years. The history and physical examination are otherwise entirely negative. I have given her 25 grains (1.6 Gm.) of quinidine sulphate daily for the past four months without toxic effects. The attacks occur less frequently and are of shorter duration. Could I safely give larger doses? Would a larger daily administration of quinidine be apt to obviate any further attacks? Over how long a period of time may I administer 25 grains or more of this drug daily? Kindly omit name.

M.D., New York.

Answer.—The dose now being given is larger than that customarily given for a maintenance dose. The average dose for a long period of time is from 10 to 15 grains (0.65 to 1 Gm.) daily. The dose given here is almost the usual maximum dose for a short period of administration. Because of its toxic action the propriety of long-continued administration except in a few selected cases is to be questioned. The dose might be increased safely, but to do so is to take an unwarranted risk. There have been a great many deaths. Parkinson and Campbell found a 4 per cent mortality in reports of cases collected from the literature. While many of the deaths were probably due to embolism, a large percentage were due to the toxic effect of the quinidine on the heart muscle or the respiratory center.

A larger dose would probably not obviate further attacks. If the dosage mentioned has been maintained already for four months it can probably be continued, as quinidine is excreted rapidly. It is a larger dose than is advisable, and the patient should be watched for toxic effects. Evidence of myocardial insufficiency has been observed in such cases which has disappeared when the quinidine has been discontinued.

The history and physical examination should be thoroughly reviewed for some possible clue to the factors inducing the attacks. A toxic thyroid especially should be ruled out. Gastro-intestinal factors frequently precipitate attacks.

REMOVAL OF TAPEWORM IN PREGNANCY—AMPUTATION OF CERVIX AND STERILITY

To the Editor:—1. Is it considered safe to try to remove a tapeworm from a pregnant woman, or shortly after delivery, by the usual means of epsom salt and male fern? Is there any safer way to get rid of it during such a time? (I have heard of a miscarriage that was presumably caused by the treatment and I have wondered what was the safest way to treat such cases, which are not infrequent) 2. How much can one depend on amputation of the cervix to prevent conception? (A former patient of mine went to America on furlough and I hear that she has had the operation done and I know she was keen on preventing further conceptions. What result may be expected?)

ELWOOD L. DAVIS, M.D., Kijabe, East Africa.

ANSWER.—1. Abortion or premature labor may occur as the result of drastic treatment for the removal of a tapeworm during pregnancy. If the patient is near term it is especially advisable to wait until after delivery before attempting the removal of the tapeworm. During the puerperium there is no harm in giving the customary drugs for tenia, but it is best to keep the baby away from the breast for one or two days after the anthelmintics are taken by the patient.

2. Amputation of the cervix is by no means a certain method of preventing conception. Many women who have this operation performed become pregnant afterward, but a certain proportion of them have miscarriages and a still larger number have dystocia during labor. If there is an infection or so-called erosion of the remaining portion of the cervix, sterility may result but even this is by no means a constant occurrence. Perhaps the patient to whom the questionnaire refers may have had a sterilization operation performed when the cervix was amputated.

LIME WATER IN INFANT FEEDING

To the Editor:—Will you please give me your opinion concerning the use of lime water in milk modifications for infants? How much calcium will be added to the milk per ounce of saturated lime water? Is there danger of including too much calcium by this addition? I would be glad to know the advantages and disadvantages of its use.

MARGARET S. CHANEY, Manhattan, Kan.

ANSWER.—Lime water is a saturated aqueous solution containing 0.14 per cent of pure calcium hydroxide. Its addition to cow's milk formulas results in inhibiting the formation of curds (paracaseinates). This action is proportionate to the amounts added. As ordinarily used, 1 ounce (30 cc.) of lime water is added to the formula for each 20 ounces (600 cc.) of milk in the mixture (that is, 5 per cent of lime water). Larger amounts have been used. Lime water is not given the serious consideration at present that it enjoyed formerly when its addition to all artificial formulas was almost routine.

OINTMENT FOR INTERSTITIAL KERATITIS

To the Editor:—I would appreciate learning the formula for Casey Wood's ointment as used for interstitial keratitic lesions.

HARRY V. THOMAS, M.D., Buckhannon, W. Va.

ANSWER.—The ointment in question was the old citrine ointment (old U. S. P. unguentum hydrargyri nitratis) with the variation that crude cod liver oil was used as a base instead of lard oil. As fuming nitric acid is used, the ointment has to be allowed to stand about six months before it is use in order to allow the acid fumes to dissipate.

Rhode Island July Examination

Mr. Lester A. Round, director of the State Public Health Commission of Rhode Island, reports the written and practical examination held at Providence, July 2-3, 1930. The examination covered 7 subjects and included 70 questions. An average of 80 per cent was required to pass. Twenty-eight candidates were examined, 27 of whom passed and 1 failed. The following colleges were represented:

College PASSED	Year Grad.	Per Cent
Georgetown University School of Medicine	(1930) 86.3,* 87.5,*	89.4*
Baltimore Medical College	(1908)	83.5
College of Phys. and Surgs., Baltimore	(1903) 80.7, (1910)	88.2
Johns Hopkins University School of Medicine	(1918)	96.4
Maryland Medical College	(1912)	82.4
Boston University School of Medicine	(1919) (1929) 90.8,	89.7
Harvard University Medical School	(1913)	88.2, (1927) 87.7, (1929) 87.8, 89.1
Tufts College Medical School	(1915)	90.6, (1919) 89.1, (1922) 84.1, (1927) 86.5, (1928) 89.2
St. Louis University School of Medicine	(1930)	87.5*
Columbia Univ. College of Physicians and Surgeons	(1925)	90.8
Jefferson Medical College	(1910)	87.1
University of Pennsylvania Sch. of Med.	(1912) 91.1, (1913)	86.1
University of Vermont College of Medicine	(1913)	86
Medical College of Virginia	(1929)	87.2
Laval University Faculty of Medicine	(1911)	86.4

College FAILED	Year Grad.	Per Cent
Baltimore Medical College	(1899)	63.2

Mr. Round also reports that 3 candidates previously examined presented evidence of completion of internship and were granted licenses. One candidate was licensed, July 10, 1930, on the basis of a National Board of Medical Examiners certificate, after having passed an oral examination. The following colleges were represented:

Georgetown University School of Medicine	(1929)	91.7†
University of Oklahoma School of Medicine	(1929)	89.4‡
Jefferson Medical College	(1929)	89.2§
University of Pennsylvania School of Medicine	(1926)	N. B. M. Ex.

* Certificate withheld pending completion of internship.

† Examined, July 2, 1929; internship completed and license granted, Aug. 2, 1930.

‡ Examined, April 3, 1930, internship completed and license granted, July 15, 1930

§ Examined, April 3, 1930; internship completed and license granted, Aug. 5, 1930.

Georgia June Examination

Dr. B. T. Wise, secretary of the Board of Medical Examiners of Georgia, reports the written examination held at Augusta, June 4 and 5, and Atlanta 11 and 12, 1930. The examination covered 10 subjects and included 100 questions. An average of 80 per cent was required to pass. Seventy candidates were examined and passed. The following colleges were represented:

PASSED

College	Year Grad.	Per Cent
Howard University School of Medicine	(1930)	88.5
Emory University School of Medicine	(1930)	86.6, 87.6, 88.6, 89.1, 89.6, 90.2, 90.3, 90.5, 90.5, 90.6, 90.7, 90.8, 90.9, 91, 91.1, 91.4, 91.4, 91.6, 91.7, 91.8, 91.9, 92.1, 92.3, 92.3, 92.8, 93, 93.1, 93.2, 93.6, 93.6, 93.9, 94.3
University of Georgia Medical Department	(1930)	87.9, 89.7, 89.7, 89.7, 90, 90.2, 90.3, 90.4, 91.3, 91.3, 91.4, 91.5, 91.5, 91.6, 92, 92.1, 92.3, 92.3, 92.3, 92.5, 92.7, 92.8, 93.1, 93.3, 93.5, 93.9, 94.1, 94.7, 94.9, 96.7
Harvard University Medical School	(1920) (1927)	91.2 92.3, 92.8
Columbia Univ. College of Physicians and Surgeons	(1930)	93.6
Jefferson Medical College	(1929)	94.1
Meharry Medical College	(1930)	91.8, 93.6

Dr. Wise also reports 7 physicians licensed through reciprocity with other states since Jan. 1, 1930. The following colleges were represented:

LICENSED BY RECIPROCITY

College	Year Grad.	Reciprocity with
Howard University School of Medicine	(1926)	Dist. Colum.
State University of Iowa College of Medicine	(1922)	Iowa
University of Louisville School of Medicine	(1880)	Missouri
Tulane University of Louisiana School of Medicine	(1926)	Alabama
Johns Hopkins University School of Medicine	(1927)	Maryland

University of Tennessee College of Medicine	(1928)	Tennessee

Book Notices

Oxidation-Reduction Potentials. By L. Michaelis, M.D., Member of the Rockefeller Institute for Medical Research. Translated from the German manuscript by Louis B. Flexner. Cloth. Price, $3. Pp. 199, with 16 illustrations. Philadelphia: J. B. Lippincott Company, 1930.

This small volume in a relatively new but rapidly increasing field of interest is the latest in the series of monographs on experimental biology, founded by the late Jacques Loeb. The monographs on experimental biology were founded to bring together the results in special fields of research in separate treatises, especially those fields in which the methods of the exact science are applied to the study of biologic phenomena. The latest member of this series is a worthy companion to its predecessors. Dr. Michaelis is perhaps best known for his contributions to experimental medicine from the point of view of the applications of physical chemistry, a number of articles on which have appeared in the scientific journals under his name, and by his monograph in German on hydrogen ion concentration, a book which holds equal rank with Clark's masterpiece on hydrogen ion concentration. Dr. Michaelis, therefore, is eminently qualified to write on the subject of oxidation-reduction applied to biology. Within the past few years the traditional concepts of oxidation and reduction have undergone extensive revisions and additions, mostly by an application of the electronic theory. The applications to biology were not slow in coming, but the present author believes that a complete and clear exposition of the subject will hasten the application of this phase of physical chemistry to the problems of physiology or, in the wider sense, experimental biology. Wisely the author states: "Up to the present not a great deal has come from the efforts to avail biology of the fruits of these and similar investigations and one must be content to look to the future. The significance of the new point of view, however, is readily appreciated for it provides a clearer and thermodynamically correct approach to cell energetics and I venture to suggest that from these modest beginnings studies of the metabolism of the living cell will be directed to a new path." The book is divided into two main parts: physicochemical considerations and physiologic applications, and the physiologically important redox (that is, oxidation and reduction) systems. The first part gives a lucid and concise account of the theoretical foundations of reversible systems in which oxidation and reduction may take place, and the second part contains an equally lucid and a more interesting account of work already published on biologic systems susceptible of more or less exact measurement. Some topics treated are: sulphydril systems, an exposition of work in the important cystein-cystine system; the hemoglobin-oxyhemoglobin system; Warburg's respiratory ferment, and luciferin. The topics treated are not of immediate interest to the medical reader; for the medical scientist and for the experimental biologist it will be welcome as the first concise account of work in this new and important field applied to ascertaining how that anomalous machine, the human body, functions with such a degree of efficiency. The author is not hesitant in saying that it does so by systems which are in a constant state of oxidation and reduction equilibrium or the transfer of electrons which cause work.

Nouveau traité de psychologie. Par Georges Dumas, professeur à la Sorbonne. Tome I: Notions préliminaires. Introduction. Méthodologie. Avec la collaboration de C. Champy, professeur à la Faculté de médecine de Paris, et al. Cloth. Price, 75 francs. Pp. 425, with 75 illustrations. Paris: Félix Alcan, 1930.

One cannot judge this ambitious treatise by the first volume. It is necessary to agree with the editor that a knowledge of zoology, anthropology, ethnology, linguistics and neurology is a desirable preliminary to the study of psychology. But such knowledge is not apt to be acquired from the chapters in this volume. Chapter 1 on the place of man in the animal series and Chapter 2 on anthropology are condensed to the point of incomprehensibility. It would have been much better simply to refer the readers to the works of Boule, Elliott, Smith, Deniker and Meillet, from which they are largely copied. Chapter 3 is more adequate and Chapter 4 is a masterly essay by an acknowledged authority in neurophysiology. Chapter 5 is again totally inadequate, the attempt to discuss the structure and special physiology of the nervous system in the space of seventy pages being doomed to failure. The remaining chapters are brief essays on the historical development and methodology of psychology.

Behavior Patterns of the Alimentary Tract. By T. Wingate Todd, M.B., Ch.B., F.R.C.S., Western Reserve University. The Beaumont Foundation Lectures, Series Number 9. Cloth. Price, $1. Pp. 79, with 12 illustrations. Baltimore: Williams & Wilkins Company, 1930.

This book represents three of the Beaumont Foundation lectures given by Dr. Todd before the Wayne County Medical Society of Detroit. It is a clear description of a study of the behavior of the alimentary canal by the roentgen method under the influence of local, reflex and emotional stimuli, such stimuli as water, milk, acid, alkali, carminatives, and heat and cold directly and indirectly applied. The study was made on more than 400 normal students and the observations were repeated on each student sufficiently often to give confidence in the behavior pattern outlined. It is a scholarly book and will be found of significant value to all workers in the physiology, pathology and therapy of the alimentary canal.

Untersuchungen über das Dunkelsehen mit Tscherning's photometrischen Gläsern. Von Hans Ulrik Möller, I. Assistent an der Augenabteilung des Reichshospitals. Paper. Pp. 149. Copenhagen: Arnold Busck, 1929.

This short monograph on dark adaptation gives an extensive and thorough review of all the literature of the subject, beginning with Aubert's work in 1865. The work includes investigations of the eye with regard to the various influences on the ultimate outcome, such as the diameter of the pupil, monocular and binocular results, and the size of the object. There are many investigations mentioned regarding the sensitivity in the various areas of the retina, the suppression of the visual acuity in reduced light and the variations of daylight. Extensive use was made of Tscherning's photometric glasses, first introduced in 1922, to vary the light intensity in applying its effects on the eye; also of Tscherning's lamprometer to measure the light intensity. Included are numerous tables and graphs regarding the ultimate results. The bibliography is practically complete, as it incorporates all the articles published to date on this subject. It is well worth the attention of ophthalmologists interested in this subject.

La vie d'Ambroise Paré (Chirurgien du Roy, écrivain). Par le Dr. Léon Michelet. Preface du le Dr. Victor Pauchet. Paper. Price, 10 francs. Pp. 160. Paris: Le Francois, 1930.

In this interesting sketch an account is given of Paré's birth in the city of Laval, of his rather lowly origin, of his early fondness for study, and also about a definite desire on his part as a youth for a surgical career. After being apprenticed to a barber in Laval for three years, during which time he learned little or no surgery, Paré went to Paris with an older brother. There he served another but a more profitable three years' apprenticeship and was able to attend the evening lectures at the Faculty of Medicine. Paré soon attracted the attention of his teachers because of his intelligence, sagacity, powers of observation and ardor for work. When there was a vacancy he was appointed compagnon chirurgien at the Hôtel-Dieu of Paris, where he spent three busy years. While there, Paré kept up his dissections and thus became a skilled anatomist. Next he is seen as an army surgeon with French troops in a campaign against the house of Austria in Savoy and Piedmont. While thus engaged, Paré found that the traditional boiling oil treatment of wounds was both painful and unsatisfactory. He substituted for it a mixture of yolk of egg, rose water and turpentine, which was quite successful. One of Paré's most audacious operations was the removal of a lance shaft from the skull of the noted Duc de Guise, using a pair of blacksmith's tongs. A number of other surgeons had given the case up, so Paré's success added much to his growing reputation. Later, he first ligated the blood vessels following amputation, which some have considered his chief contribution to surgery. In 1552, Henry II appointed him as one of his surgeons. Paré was taken a prisoner by the Spaniards but was released without paying ransom because he cured an obstinate leg ulcer for one of their leading captains. Late in 1554 he became a member of the College royal des chirurgiens. After the death of Henri II Paré served as surgeon to Francis II, Charles IX and Henry III. He was particularly well liked by Charles, who saved him, even though a Protestant, from the massacre of St. Bartholomew's. In 1569 that monarch sent him to treat the Marquis d'Auret, a prominent nobleman at Mons. Paré incised and drained a severe infection following a bullet wound and thus effected a cure where several others had failed. This result brought him recognition from the highest circles. As before, he continued to treat the rich and the poor without distinction. Paré cared for Admiral Coligny just before his assassination during the massacre of St. Bartholomew's. Paré wrote extensively, especially on surgery. He died in 1590, being 81 years old, after a busy career devoted to the relief of human suffering. This monograph is warmly recommended to those who wish to learn about the career of one who has been termed by not a few the Father of Surgery.

A Compilation of Culture Media for the Cultivation of Microorganisms. By Max Levine, Ph.D., Professor of Sanitary and Technical Bacteriology, Bacteriologist, Iowa Engineering Experiment Station, and H. W. Schoenlein, M.S. Cloth. Price, $15. Pp. 969. Baltimore: Williams & Wilkins Company, 1930.

This compilation was made at the request of the Society of American Bacteriologists. The authors searched the standard periodicals of both Europe and America from their beginning to the year 1926, as well as textbooks, monographs, bulletins and other periodicals. They found about 7,000 formulas for culture mediums and these they have arranged and classified into about 2,500 distinct mediums each of which is described as to its constituents, preparation, sterilization and use. The mediums are numbered consecutively, the last one being number 2543. Then follows an index of constituents of mediums; for example, cumumber juice is used in medium 2128; beef is used in fifty-one different mediums and the page on which each of these is described follows the word beef in the constituent index. Next comes the author index, and following that a list of names of persons who first described a particular medium with the reference in the medical journal in which the original article appeared. This is a handy arrangement of a lot of material which was scattered through the libraries and, as far as known, had not been collected and indexed in such fashion before. The authors and the Society of American Bacteriologists deserve credit for undertaking this work. It shows clearly how far the science of bacteriology has advanced since Robert Koch first prepared solid culture mediums.

Unspezifische Therapie und natürliche Abwehrvorgänge. Von Dr. Ferdinand Hoff, Privatdozent für innere Medizin an der Universität Erlangen. Paper. Price, 7.80 marks. Pp. 123, with 15 illustrations. Berlin: Julius Springer, 1930.

During the course of the past few years there have appeared in the German medical literature not only sharp criticisms of our entire therapeutic approach—and this from excellent clinicians—but searching inquiry into the philosophic background as well as the aims, methods and results. As an accompanying manifestation, a number of interesting monographs have appeared that deal with therapy from the nonspecific point of view: Among these, the book of Königer on "Krankenbehandlung durch Umstimmung" as well as this new one of Hoff. It is perhaps to be regretted that here in America the older review of Petersen's has not been followed by a comparable interest in a field that is of wide biologic and therapeutic interest. This monograph is most interesting because it takes up in considerable detail the theoretical background that underlies not only therapy by means of nonspecific agents but the therapeutic effect of diet as well. He makes clear the importance of the interval and the phase in treatment, and the chapter on the relation of the skin as a therapeutic approach presents much that is new and valuable. It is not a book for the "busy practitioner." It is a treatise that is of real value to the pharmacologist—but will probably not be read by the pharmacologist because it has little to say of drugs—to the therapeutist, and to medical men who find pleasure in taking therapeutic problems and observations which they constantly meet in the practice of medicine and unraveling them along lines that seem biologically rational.

A Synopsis of Surgery. By Ernest W. Hey Groves, M.S., M.D., B.Sc., Surgeon to the Bristol General Hospital. Ninth edition. Cloth. Price, $5 net. Pp. 676, with illustrations. New York: William Wood & Company, 1930.

The author has attempted to include the important points of surgical practice in a brief synopsis. It is not meant to replace surgical textbooks but to supplement them by offering the student an opportunity to review the entire subject and to permit the busy practitioner to get a general and systematic survey of modern surgical practice. In this edition the work has been revised and brought down to date, with the inclusion of a number of new methods of treatment. The arrangement of a standard textbook is followed, but the outline form is used and only a few of the salient points are given under each heading. Some of the main subjects taken up are inflammation, acute and chronic infections, tumors, wounds and their treatment, anesthesia, and diseases and injuries of the various systems of the body. The various regions of the body, including the viscera, are then taken up in the same manner and the various surgical diseases and injuries are outlined. The amount of material included is enormous, because of the large field covered. It would seem difficult to improve this synopsis without making it so elaborate that it would lose its purpose. Fairly numerous diagrams and illustrations are included.

Essais et dosages biologiques des substances médicamenteuses. Par Jeanne Lévy, docteur ès sciences physiques. Préface du Professeur Tiffeneau. Paper. Price, 28 francs. Pp. 148, with 15 illustrations. Paris: Masson & Cie, 1930.

This small book on bio-assay is divided into three parts. The first part discusses general principles. The second part takes up the substances now recommended for systematic biologic standardization by the Committee of Hygiene of the League of Nations, which aims at the development of international units. It deals with the digitalis series, epinephrine, hypophysis, ergot, arsphenamines, insulin, thyroid and anthelmintics. The third part is devoted to the biologic standardization of substances not yet considered by the international commission: antipyretics, miotics and mydriatics, vasoconstrictors and vasodilators, local anesthetics, and a mixture of the opium alkaloids.

The Action of Muscles Including Muscle Rest and Muscle Re-education. By Sir Colin Mackenzie, M.D., F.R.C.S., F.R.S., Professor of Comparative Anatomy and Director of the Australian Institute of Anatomy, Canberra. Second edition. Cloth. Price, $3.50. Pp. 288, with 100 illustrations. New York: Paul B. Hoeber, Inc., 1930.

This is a scholarly, timely and useful monograph. While the author is a professor of anatomy he is clearly a functional anatomist, and the book will be a valuable aid to the surgeon, the internist and the physical therapist who are dealing with the various types of muscle paralysis brought on by physical trauma or disease. The illustrations are clear, well selected, and helpful. The practical character of the book may be illustrated by the following quotations:

> The function of muscle, the all important factor, cannot be successfully taught in the dissecting room; it can only be taught on the living and is largely a question of comparison, a comparison between the normal and the paralytic. Only on this plan can the question of origin and insertion of muscle have more than academic interest for the student and the practitioner.
>
> What significance the expression massage and electricity has in the surgeon's mind the writer has often longed to know. In poliomyelitis no massage or electricity should be applied till recovery has taken place. These forms of treatment cannot initiate muscle function, but they can strengthen the action of recovered muscles. The principle cannot be repeated too often that an ounce of scientifically directed volitional effort is worth pounds of passive treatment. With this in mind it is wonderful what can be accomplished in a warm room with the aid of a table, a few pillows, and a sheet of powdered cardboard. Such indeed might be termed the Department of Myology. To this simple department the more complex ones of massage, electricity, and of those movements which owe their name sometimes to the country of origin and sometimes to their inventor, should be subsidiary. The myologist, looking at the case solely from the point of view of function, should determine whether in traumatic cases, at what stage, and of what nature, massage or electrical treatment or both would be beneficial. These should not be ordered indiscriminately and as a matter of routine.

Die Behandlung des Hallux valgus. Von H. Timmer, Privatdozent für orthopädische Chirurgie an der Universität zu Amsterdam. Paper. Price, 4.50 marks. Pp. 62, with 21 illustrations. Leipzig: Johann Ambrosius Barth, 1930.

The author gives an orderly detailed description of the pathologic processes and etiologic factors in hallux valgus. He then describes the indications for correction of this deformity. Line drawings illustrate the various operative procedures described during the past fifty years, consisting of resections of the proximal phalanx or parts of it; the head of the first metatarsal or portions of it; resections of parts of the shaft of the first metatarsal; osteotomy of the first metatarsal; resections of the first cuneiform metatarsal joint; wedge resections of the first cuneiform bone; operations on the sesamoids, tendons and capsules, and combinations of the foregoing. The conservative, bloodless treatment for moderate cases by manipulation, splints, plaster of paris and shoes is described. Timmer concludes with remarks on the necessity for varying the type of treatment according to the indications. This little volume is worthy of study by orthopedists as well as by the general surgeon. It will impress on the reader the fact that this deformity should not be considered lightly.

Handbuch der inneren Sekretion: Eine umfassende Darstellung der Anatomie, Physiologie und Pathologie der endokrinen Drüsen. Band II, Lieferung 7. Herausgegeben von Dr. Max Hirsch. Paper. Price, 7 marks. Pp. 1429-1492. Leipzig: Curt Kabitzsch, 1930.

This section of the larger work contains three brief chapters on the general problem of fat metabolism as related to the endocrine glands. There is a chapter on morphology or, rather, the occurrence of fats in the endocrine glands themselves by Dr. Bererich and Dr. Jaffe; a short chapter by Dr. Handovsky on the chemistry of the aliphatic lipoids; and a somewhat longer chapter by Drs. Westphal and Mann of Hanover on the clinical physiology and pathology of fat metabolism. This chapter is the most important in the present section. The authors deal particularly with the disturbances in the lipoids associated with changes in the endocrine glands, such as the change in the distribution of fats in the female on puberty, the decrease in the blood cholesterol during gestation in mammals, and the increase in blood cholesterol in hypothyroidism and the lipemia of diabetes. The authors are to be commended on their brevity in theorization, with the present dearth of accurate information of the mechanism of lipoid changes in all these conditions. They conclude (p. 1475) that "we must assume that the endocrine glands influence lipoid metabolism just as they influence fat and carbohydrate metabolism, but our present knowledge does not furnish an explanation of the manner or mechanism of this influence."

Klinik und Therapie der Alterskrankheiten dargestellt für den Praktiker. Von Hofrat Professor Dr. Hermann Schlesinger, Vorstand der 3. medizinischen Abteilung des allgemeinen Krankenhauses in Wien. Paper. Price, 6 marks. Pp. 132. Leipzig: Georg Thieme, 1930.

This modest and inexpensive little volume is designed for the medical practitioner. Theoretical considerations are largely eliminated. The main disorders associated with old age are briefly described, differential diagnoses given, and therapies outlined, with the author's experience and success and failures for the different methods of management. The little monograph bears the imprint of a sane and sound medical practitioner with wide experience. In no place does Professor Schlesinger appear to have fallen a victim to the fads of the hour. The modern so-called rejuvenation is briefly discussed. Dr. Schlesinger questions the value and the safety of the Steinach or the Voronoff operations. He remarks, "I have studied many patients subjected to the rejuvenation operation of Steinach but I have practically never seen the physical or mental improvement that optimistic physicians so frequently describe." While the monograph cannot be classed in the group of major contributions to the art of medicine, practitioners will find it a useful and helpful guide.

Manual of the Diseases of the Eye for Students and General Practitioners. By Charles H. May, M.D., Consulting Ophthalmologist to the Mt. Sinai Hospital, to the French Hospital, to the Italian Hospital, New York, and to the Monmouth Memorial Hospital. Thirteenth edition. Cloth. Price, $4 net. Pp. 461, with 374 illustrations. New York: William Wood & Company, 1930.

This is a revision of the well known compend of eye diseases, with the addition of some new plates and a chapter on the slit lamp and corneal microscope, written by T. Harrison Butler for the sixth British edition. The arrangement is the same as in previous editions, the anatomy and physiology of the structure being given at the beginning of each chapter, followed by the various clinical entities, each one being discussed under varieties, subjective symptoms, objective symptoms, complications, etiology, prognosis and treatment. Operative procedures are described in the chapter dealing with the disease and not in a separate chapter on operations. Chapter XXVI deals with general principles of eye surgery and preparation of the eye for operation as well as ocular therapeutics. The final chapter deals with ocular manifestation in general disease. The book is a compact work on the essentials of ophthalmology. While brief and of little interest to the ophthalmologist, it serves a useful rôle for the medical student and the general practitioner.

Die wissenschaftlichen Grundlagen der Hunger- und Durstkuren. Von Dr. Hans Günther, Professor an der Universität Leipzig. Paper. Price, 8 marks. Pp. 171. Leipzig: S. Hirzel, 1930.

This is a fairly useful treatise on an old subject. The practice of curing disease by fasting runs back to the earliest records of medical therapy. At certain periods the fasting cure has been applied to almost every known malady and there has not been lacking development of this therapy in the direction of fads and cultism. Dr. Günther presents fairly complete historical accounts of the fasting cures. He presents conditions today under which the good doctor may use short periods of complete fasting or periods of undernutrition as useful adjuncts to other therapies. There is no faddism in the book. For example, Dr. Günther says on page 58 that fasting is an unnecessary procedure in adiposity. There are other adequate methods of handling most of these conditions. In rheumatism there is no doubt that in many cases the patient's symptoms are improved by a period of fasting. The symptoms, however, are apt to return on realimentation. The second part of the monograph deals with so-called thirst cures. Dr. Günther uses this term essentially in the sense of dry diets, that is, diets deficient in water. The author ends with the plea (p. 93) for more critical study of the value and the mechanism of the temporary improvement of symptoms by fasting in various diseases.

La rate organe réservoir. Par Léon Binet, professeur agrégé de physiologie à la Faculté de médecine de Paris. Paper. Price, 20 francs. Pp. 116, with illustrations. Paris: Masson & Cie, 1930.

This is a concise and scholarly account of knowledge of the contractivity of the spleen. It is now well established that the spleen acts as a considerable reservoir for the blood, that the musculature of the spleen is so arranged that its contraction forces this blood into the general circulation, and that its relaxation withdraws considerable blood from the general circulation. Binet outlines and describes experiments showing the nervous and humoral mechanisms of this motor behavior of the spleen. A useful and reliable monograph.

Medicolegal

Infringement of Copyright of Medical Papers

(Schellberg v. Empringham (U. S.), 36 Fed. (2d) 991)

One Oscar Boto Schellberg was the president and manager of an institution bearing his name, where treatments known as "colonic therapy" were administered. In June, 1922, an article written by him was published in the *International Journal of Surgery*, entitled "The Incorrigible Colon Corrected by Medicated Irrigation." In January, 1923, another article by Schellberg appeared in the same publication, entitled "Technique of Colon Irrigation." The issues of the *International Journal of Surgery* containing Schellberg's articles were copyrighted by the International Journal of Surgery Company. So far as the copyrights covered Schellberg's particular articles, they were obtained with his acquiescence and held in trust for him. Schellberg procured a number of reprints of his articles, and they were taken to his colonic institute. From time to time they were distributed to his patients and to physicians and other persons. Copies were kept on a stand in the reception room of the institute, where they might be examined or carried away by visitors. The primary purpose of the distribution of these reprints was, it was said, to give information to persons interested in the subject discussed in them and to relieve Schellberg of the necessity of orally explaining his system of treatment to those who might wish to learn about it. None of the reprints carried a notice of copyright of the printed material, but each of them carried an inscription on its cover to the effect that it was a reprint of an article which had appeared in the *International Journal of Surgery*. In 1923, Schellberg developed the subject-matter of his previous articles into a copyrighted book, entitled "Colonic Therapy in the Treatment of Disease."

The defendant Empringham was an Episcopalian minister. He was, in 1924, the superintendent of the Church Temperance Society, closely identified with which was another corporation, the Health Education Society, Inc. In September, 1924, Empringham published a book entitled "Intestinal Gardening for the Prolongation of Youth." It contained a considerable amount of material copied bodily from the *International Journal of Surgery* reprint, for which due credit was given to Schellberg and the *Journal*. It contained also certain cuts that Empringham had obtained from Schellberg. In a later edition of Empringham's book, however, most, if not all, of Schellberg's material that had appeared in the previous edition was incorporated, but none of it was credited to Schellberg. Schellberg thereupon brought suit in the U. S. District Court, S. D., New York, against Empringham and the Health Education Society, Inc., based on the infringement.

Empringham's defense was predicated principally on the contention that his copying had been done from the reprints from the *International Journal of Surgery* and not from Schellberg's book. No copyright protection applied to such reprints, he claimed, because they carried no copyright notice. Moreover, he claimed, such protection as might have been afforded Schellberg's articles by the copyrights on the magazines in which they originally appeared was abandoned when the reprints were publicly distributed. Further defenses, not material to present purposes, were that Schellberg authorized Empringham to copy the reprints and that Empringham, before he began his infringement, had no notice of a copyright on Schellberg's articles.

Coming to the question as to whether the distribution of the unmarked reprints constituted an abandonment of the copyright, said the court, it is to be remembered that such reprints were freely distributed to persons who visited the Schellberg Institute. It is fair to assume that the number distributed was fairly large. The reprints, which are of considerable length, were presumably carried away from the institute for perusal and studied by persons who obtained them. Notwithstanding all this, the court concluded that Schellberg should not be held to have dedicated his articles to the public. The distribution of his reprints which he made and which he authorized Empringham to make was for a specific and limited purpose; namely, for the instruction of the persons who, as prospective patients of the institute, might be interested in the subjects which the articles discussed. The slavishly copied matter taken from Schellberg, whether regarded as having been lifted from Schellberg's articles or from his book, was sufficient, the court concluded, to make out a case of infringement. Judgment was therefore awarded against Empringham and the Health Education Society, Inc., and against the publisher of the second edition of Empringham's book.

Ludwig's Angina After Dental Extraction an Accident

(International Travelers' Ass'n v. Francis (Texas), 23 S. W. (2d) 282)

Marvin Lee Francis employed a regularly licensed practicing dentist to extract a wisdom tooth, rather deeply embedded in the gum. At the time of the extraction there was no swelling of the gums, no redness and no pus. It was necessary to go deeper into the tissues to effect extraction than is ordinarily the case. Infection followed promptly. Within three days, the mouth and gums were badly and perceptibly involved, and in eight days the patient was dead. His life was insured by a mutual assessment accident insurance company, in a policy providing for the payment of $5,000 in event of death caused "solely and exclusively by external, violent and accidental means." Suit was brought to collect the insurance money payable under the policy. The trial court found that the death was accidental but denied recovery because of failure to give proper notice of the death. The court of civil appeals likewise found that the death was accidental but, having concluded that the notice of death was given as required, reversed the judgment of the trial court and rendered judgment in favor of the beneficiary under the policy. The case was thereupon appealed to the Supreme Court of Texas.

The drawing of the tooth and the treatment following, said the Supreme Court, were of course purposeful and not accidental, but the infection was not the necessary or usual result of this purposeful act. It was extraordinary, unusual and very rare. The proper surgical act therefore must have been accompanied by something unexpected, unforeseen and improbable. This unforeseen, unexpected and improbable thing was the injection of the pathogenic organisms into the tissues. Just how they were injected the evidence does not show with mathematical precision, and in the nature of things this can never be done in any case. That they were introduced into the tissues at the time of and as a part of the surgical act of extracting the tooth and treating the lacerated tissues seems to be a logical deduction from the facts proved. The infection was caused either by the entrance of germs on the dental instruments used, or from cotton used by the dentist in his treatment, or by some other means; but at all events germs found their way into the tooth socket, did their deadly work and produced an unusual, unlooked for and unforeseen result, death. There was, in fact, no serious contention but that the death of the insured was "accidental."

The policy, however, did not insure the deceased against accidental death; it insured him only against death caused "solely and exclusively by external, violent and accidental means." The insurer pointed out that there was a distinction between policies which insure against accidental death and policies insuring against death by accidental means. The Supreme Court, however, reached the conclusion that the death was due to "accidental means," within the meaning of the policy, by the following reasoning:

> In order, however, for the recovery on the policy to be affirmed, we *must conclude that the death was produced by accidental means.* We have concluded that it was so produced. There can be no doubt but that the extraction of the tooth was the "means" of infection. This is so regardless of the question as to exactly how and when the pathogenic organisms entered the tissues — whether by contact with the surgical instruments and dressings, and thence into the lacerated tissues, or whether *from some other attendant source. The fact is there was no* infection until the flesh was lacerated by the pulling of the tooth, and the infection followed so closely that we cannot in a practical consideration of the subject separate the time of infection from the time of laceration; nor have the doctors attempted to do so, as shown by their testimony above quoted. In fact, they regard the drawing of the tooth as the cause of the infection. If we consider the drawing of the tooth as the means of infection, then clearly that means was external, violent, and accidental.

The judgment of the court of civil appeals in favor of the beneficiary under the policy was therefore affirmed.

Damages for a Broken Hypodermic Needle

(Alonzo v. Rogers (Wash.), 283 P. 709)

The patient, Alonzo, applied to the defendant, a dentist, to have a tooth extracted. The dentist undertook to inject into the gum, through a hypodermic needle, a suitable anesthetic. In the course of the injection, the point of the needle broke off in the patient's gum. Although a roentgenogram showed approximately the position of the part of the broken needle, all efforts to remove it, even an operation under a general anesthetic, were unsuccessful. The broken part of the needle, it was claimed, had worked upward into the roof of the patient's mouth and caused him much suffering. He sued the dentist, and judgment was rendered in his favor. Thereupon the dentist appealed to the Supreme Court of Washington.

The patient attributed the breaking of the needle to negligence on the part of the dentist. The dentist, however, asserted that it was due to careless movements on the part of the patient, notwithstanding that he had been cautioned not to move. Neither the patient nor his wife, who was with him when the needle was broken, spoke English intelligently, but through an interpreter they denied that the dentist had cautioned him. A dentist, testifying for the defendant, said that in his experience it was not unusual for a needle to break while being used for the injection of fluid to produce local anesthesia. Other dentists called by the defendant testified that the needle used was a standard one, but that, because of the delicacy of the instrument, a needle would sometimes break and become lodged in the mouth of the patient, notwithstanding the utmost care and skill on the part of the operator. One of the expert witnesses called by the defendant testified, however, that a needle is a delicate instrument, "if it isn't used right." There was testimony to the effect that the treatment adopted by the dentist after the accident conformed to that followed by competent dentists. On behalf of the dentist, it was argued that the evidence was not sufficient to warrant the jury in finding that he was negligent in any such substantial degree as to render him liable for the injury, since the only direct evidence was that concerning the injection and the breaking of the needle. The Supreme Court, however, took a different view and held that, considering the degree of care with which the defendant was charged in the use of the hypodermic needle, and in view of his undertaking as a dental surgeon to treat the patient, the evidence presented a question of fact for the jury and warranted it in believing that negligent manipulation of the needle by the defendant caused it to break. We are not unmindful, said the court, of the testimony of one of the dental witnesses, that the needle is a delicate instrument, "if it isn't used right." The testimony that such occurrences are not unusual was not such as to compel the jury to find that the needle was not so negligently manipulated while in the patient's gum as to cause the needle to break. The evidence showed that the needle was of a standard type, and that no injurious results would be expected unless from careless use of it by the operator or unless the patient moved his head during the operation. Both inspection and use of the needle were at the time under the exclusive control of the dentist. While the testimony was conflicting as to whether the patient moved his head and thus broke the needle, the jury found that he did not do so. There was no testimony that the breaking of hypodermic needles by dental surgeons in the gums of their patients was of frequent occurrence. The Supreme Court concluded:

> Surely such results are unnecessary and are not to be anticipated if the proper degree of care is exercised by dental surgeons. If such accidents were frequent, the dentists would quit using hypodermic needles and employ some other method for deadening pain.

The judgment in favor of the patient was affirmed.

Evidence: Expert Witnesses.—Many physicians of well known ability and standing testified as witnesses for the appellant that, in their opinion, the appellee's paralysis did not result from the blows described by him. The record, however, also contains the testimony of a physician who testified as a witness for the appellee, whose opinion differed from that of the appellant's witnesses. *However much we may be impressed by the* evidence of the physicians who testified for the appellant, says the Court of Civil Appeals of Texas, Eastland, we cannot say that their opinion was clearly right and that the contrary opinion of the physician testifying for the appellee was clearly wrong. That is a question of credibility and weight of which we are not to judge. The jury clearly could accept the opinion of one expert rather than the contrary opinion of many experts. To hold otherwise would be tantamount to holding that a jury's verdict, in order to be upheld, must be in favor of the party offering the greater number of expert witnesses to testify as to his contention.—*Texas Employers' Insurance Association v. Clark (Texas), 23 S. W. 405.*

COMING MEETINGS

American Academy of Ophthalmology and Otolaryngology, Chicago, October 27-31. Dr. W. P. Wherry, Medical Arts Building, Omaha, Secretary.

American Academy of Physical Therapy, Boston, October 22-24. Dr. Thomas L. Smyth, 111 North Eighth Street, Allentown, Pennsylvania, Secretary.

American Association of Railway Surgeons, Chicago, November 5-7. Dr. Louis J. Mitchell, 29 East Madison Street, Chicago, Secretary.

American College of Surgeons, Philadelphia, October 13-17. Dr. Franklin H. Martin, 40 East Erie Street, Chicago, Director-General.

American Hospital Association, New Orleans, October 20-24. Dr. Bert W. Caldwell, 18 East Division Street, Chicago, Executive Secretary.

American Physical Therapy Association, Chicago, Oct. 6-10. Dr. C. C. Vinton, 1650 Broadway, New York, Secretary.

American Public Health Association, Fort Worth, Texas, October 27-31. Mr. Homer N. Calver, 370 Seventh Avenue, New York, Executive Secretary.

Association of American Medical Colleges, Denver, October 14-16. Dr. Fred C. Zapffe, 25 East Washington Street, Chicago, Secretary.

Central Association of Obstetricians and Gynecologists, Kansas City and Excelsior Springs, Missouri, October 9-11. Dr. E. D. Plass, University Hospital, Iowa City, Iowa, Secretary.

Central States Pediatric Society, Memphis, Tenn., November 7-8. Dr. A. H. Parmelee, 310 South Michigan Boulevard, Chicago, Secretary.

Delaware, Medical Society of, Dover, Oct. 14-15. Dr. W. O. La Motte, Medical Arts Building, Wilmington, Secretary.

Medical and Surgical Association of the Southwest, El Paso, Texas, November 6-8. Dr. W. Warner Watkins, Box 1587, Phoenix, Ariz., Secretary.

Mississippi Valley Conference on Tuberculosis, Rockford, Ill., October 14-16. Dr. Robinson Bosworth, Box 1005, Rockford, Secretary.

Missouri Valley, Medical Society of the, Des Moines, Iowa, October 15-17. Dr. Joseph D. McCarthy, 107 South Seventeenth Street, Omaha, Secretary.

Pennsylvania, Medical Society of the State of, Johnstown, Oct. 6-9. Dr. Walter F. Donaldson, 500 Penn Avenue, Pittsburgh, Secretary.

Southern Medical Association, Louisville, Ky., November 11-14. Mr. C. P. Loranz, Empire Building, Birmingham, Ala., Secretary.

Virginia, Medical Society of, Norfolk, October 21-23. Miss Agnes V. Edwards, 104½ West Grace Street, Richmond, Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Issues of periodicals are kept on file for a period of five years only. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending, but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.
Titles marked with an asterisk (*) are abstracted below.

American Journal of Public Health, New York

20: 815-923 (Aug.) 1930

Significance of Thermophilic Bacteria in Pasteurized Milk. L. A. Rogers and W. C. Frazier, Washington, D. C.—p. 815.
*Hygiene of Towel. H. D. Pease and L. C. Himebaugh, New York.—p. 820.
Problems in Public Health Administration. F. C. Ruhland, Syracuse, N. Y.—p. 833.
Report of Visits to Local Registrars of Vital Statistics in Maryland. J. Collinson, Baltimore.—p. 839.
Elusive Features in Epidemiology of Common Cold. W. H. Frost, Baltimore.—p. 843.
Hospital Facilities for Treatment of Cancer. S. M. Wood, New York.—p. 849.

Hygiene of Towel.—The results of the investigation made by Pease and Himebaugh show some of the effects of the use or misuse of towels and the important part towels may play in the spread of bacteria which may be of disease-producing types. Although public health officials have recognized that the skin, especially that of the hands, may be one of the most important modes of transfer of disease-producing organisms, and that diseases other than those of known bacterial origin *may also be readily carried by the same means,* the part played by the misuse of towels and the relative merits of types of towels have not received so much attention. Tests to secure evidence regarding these points indicate that: Bacteria are transferred from the hands to the towel in surprisingly large numbers. Bacteria are readily transferred from one user to another through the medium of the towel. Most of the common disease-producing bacteria, even though in a dry state, may remain alive on the towel for at least twenty-four hours and generally *longer, making the common towel a constant and* continued source of danger. When the towel is used repeatedly by the same individual the numbers of bacteria on and in it are increased and some of these in turn may be restored to the hands of the user. Potential danger exists of a possible reinfection of the hands with disease-producing organisms left on the towel by prior use. Repeated drying with an individual towel is not a good sanitary practice. The Turkish towel, owing to its construction and a consequently greater number of points of *contact with the skin, removes greater numbers of bacteria and* dirt particles from the skin than the huck towel or the paper towel.

*Unusual Addison's Syndromes. A. B. Brower, Dayton, Ohio.—p. 166.
History of Certain Medical Instruments. L. Clendening, Kansas City, Kan.—p. 176.

Association of Chronic Ulcerative Colitis and Multiple Polyps.—According to Bargen and Comfort, polyposis of the large intestine is present in 10 per cent of cases of chronic ulcerative colitis. It occurs after severe colitis or in long-standing, slowly progressing colitis in which there is a tendency to recurrent severe exacerbations of the disease. The polyps contain large amounts of inflammatory tissue. Proctoscopic examination is the best means of diagnosis in most cases. Roentgenologic examination gives valuable information in many cases. The authors have had an opportunity to see patients in severe exacerbations of bacterial chronic ulcerative colitis, with formation of polyps later, and finally with malignant disease. Studies are under way to trace the formation of the polyps and their subsequent course in a large series of specimens obtained at operation and at necropsy.

Etiology of Gallstones.—Walsh and Ivy summarize the results of their observations as follows: Human gallstones of the mixed cholesterol variety are dissolved when placed in the gallbladder of the dog. A diffuse fibrous cholecystitis prevents the solution of the gallstone, which is due to the failure of such a gallbladder to concentrate the bile. Concentration of the dog's bile is necessary for solution of the gallstone. They were unable to show that the addition of olive oil or coconut oil to the diet significantly altered the rate of solution of the stone. However, this does not show that such vegetable oils might not be of prophylactic value, since the presence of the gallstones in the gallbladder caused changes in its histologic appearance. Biliary stasis, if it leads to a definite cholecystitis in the dog, definitely delays the solution of the gallstone. Biliary stasis leads to histologic changes in the gallbladder of the dog. The difference in the cholesterol content of dog's bile and human bile per se does not explain why dog's gallbladder bile dissolves the human gallstone. Soap, especially the soap of lauric acid, is a potent solvent of cholesterol and the mixed type of human gallstone. There is a marked difference between the cholesterol-saponifiable ratio in human bile and dog bile, which, the authors believe, explains why gallstones of the cholesterol variety have never been produced in the dog and why the dog's gallbladder dissolves the human gallstone. They have not proved this, however.

Use of Stramonium in Postencephalitic Syndrome.—Jacobson and Epplen regard stramonium as a valuable drug in palliation of the parkinsonian syndrome and associated symptoms. Very large doses are necessary. Toxic manifestations are rare and seemingly evanescent. Fresh preparations should be demanded. Particular caution is necessary against substitution of belladonna for stramonium. There are probably at present unknown alkaloids present in stramonium. The authors have been using U. S. P. standardized preparations, specifying a fresh preparation, in doses beginning in adults with 20 measured minims, three to four times daily, until an optimal dosage is reached, which is usually around 60 measured minims, four times daily, to get the best results. In a few cases sufficient tolerance has developed so that the dose has had to be increased after a few months. This has been progressive in these cases. Sixty minims has been increased to seventy, then to 80 and then to 90 minims. Sometimes the relief from tremor in parkinsonian syndromes is only slight when stramonium is used in spite of striking benefit to the rest of the symptom complex. In these cases it is well to add scopolamine to the medication. Their routine, after the optimal dose of stramonium is ascertained and tremor has not satisfactorily subsided, is to add *scopolamine, 1/150 grain, once or twice daily increasing first to* 1/120, then to 1/100, later to 1/75 and occasionally to 1/60 grain once or twice daily until the maximal inhibition of tremor is attained or until toxic manifestations preclude large doses. Occasionally the larger doses given twice a day are necessary. Scopolamine, however, does not relax the muscular rigidity and other symptoms nearly as well as does stramonium. Toxic manifestations from stramonium have been noted. Nausea prevented one case of parkinsonism from continuing. Mydriasis is always present and troublesome for a time.

Unusual Addison's Syndromes.—In two cases reported by Brower, Addison's syndrome was related to agenesia and hypoplasia of the suprarenals in one case, and to pressure atrophy of the suprarenals produced by congenital polycystic kidneys in the other case.

27: 275-318 (Aug.) 1930

Peace and Epilepsy. C. S. Bluemel, Denver.—p. 277.
Congenital Clubfoot: Treatment. R. G. Packard and H. I. Barnard, Denver.—p. 281.
*Intravenous Injection of Sodium Chloride Solutions. P. R. Farrington, Boulder.—p. 287.
Natural Periods of Reproductive Cycle in All Placental Mammals Including Man. T. M. Burns, Denver.—p. 290.
Exploration and Certain Operations on Female Pelvis Through Cholecystectomy Incision. C. E. Tennant, Denver.—p. 295.
Acute Anterior Poliomyelitis: Infantile Paralysis. B. B. Jaffa, Denver.—p. 297.

Intravenous Injection of Sodium Chloride Solutions.—Farrington calls attention to the fact that edema and albuminuria may be produced by the intensive administration of sodium chloride solutions intravenously. The benefit derived from the use of physiologic solution of sodium chloride in relieving toxemia is as great as that obtained from the use of hypertonic saline solutions, provided a sufficient volume is given. Physiologic saline solutions are less apt to cause a reaction, or a thrombosis, and are of greater value in dehydration. Hypertonic solutions of sodium chloride should be used when it is necessary to administer large amounts of salt in the preoperative preparation of emergency cases. Isotonic solutions of dextrose should be used in the treatment of dehydration and toxemia when there is evidence of excessive tissue or blood chloride.

Effect of Intraperitoneal Injection of Potassium Iodide on Proliferative Activity of Thyroid Gland in Rats.—Chouke asserts that the intraperitoneal injection in daily doses of 0.005 Gm. and 0.025 Gm. of potassium iodide in rats for periods of ten, fifteen, twenty and thirty days does not cause any appreciable change in the proliferative activity of the thyroid gland, nor does it produce any noticeable change in the structure or character of the colloid of this organ. The average number of mitoses in the normal thyroid gland of rats is slightly lower than in guinea-pigs. The effect of administration of potassium iodide in the rat is therefore different from that observed in the guinea-pig. There is some indication that, in general, the thyroid gland of the rat is less responsive than the thyroid gland of the guinea-pig to various kinds of stimulation.

Differential Diagnosis of Rheumatoid and Ostearthritis: Sedimentation Reaction and Its Value.—The distinct clinical value of the determination of the sedimentation rate of the erythrocytes is emphasized by Dawson et al. in the differential diagnosis of rheumatoid and ostearthritis. However, the test should never be relied on as the sole criterion in the differential diagnosis of the two conditions. This differentiation can usually be made on clinical grounds alone. The determination of the sedimentation time of the red blood cells usually confirms the diagnosis and contributes information of considerable prognostic value in the clinical study of the disease.

Specific Vaccine Treatment of Chronic Arthritis and Rheumatism.—Crowe has used vaccines in the treatment of several thousand cases with steadily improving results. He says that vaccine treatment should not be used only as a last resort in advanced arthritis and rheumatism, where crippling deformities may prevent complete functional cure, but that the method should also be adopted in early cases, in which it is almost invariably successful.

Biologic Products of Streptococcus Cardioarthritidis.—The possibilities of an aqueous extract of *Streptococcus cardioarthritidis* in the treatment of rheumatic fever, as well as chronic atrophic and hypertrophic arthritis, are discussed by Small. In its use the importance of regulating dosage so as to avoid focal and general reactions is emphasized. The present development of the author's technic and its application is recorded. These products and the methods of their therapeutic application are to be regarded as in the developmental stages, so that further modifications are to be expected. A special technic is necessary in the use of the antiserum of *Streptococcus cardioarthritidis* in the treatment of rheumatic fever in order to avoid the undesirable "focal reaction" following serum administration. This technic is presented in detail.

Allergic Joint.—Freiberg and Dorst believe that they have demonstrated the experimental production of an allergic lesion in the joints of rabbits. In cases of joint disease in the human being, they encountered a lesion similar to those produced in rabbits. They are not satisfied that any previous explanation of this type of joint lesion in human beings is adequate. They believe that this lesion in the human being is also allergic and that they have demonstrated the relationship between antigenic substances from distant foci and the diseased joint. The success of treatment, which consists, essentially, in desensitizing patients to autogenous antigens which give positive reactions, seems to justfy this conception.

Angina Pectoris Including Coronary Thrombosis.—Ninety-three cases are analyzed by Wilson. Aortic enlargement was present in 31 cases. As far as etiology is concerned, infection seems to play an important rôle. To syphilis has been attributed too much significance in this connection. There were only 5 positive Wassermann reactions out of 44 tests that were made. The average pulse rate in the series was 82. Irregularity of the heart was not common, only 9 cases of premature systoles and 2 cases of auricular fibrillation being noted. In the series of cases, those presenting substernal pain alone numbered 21; substernal and down the left arm only, 43; substernal and down the right arm alone, 2; substernal and down both arms, 26; substernal and radiating to the neck, 7; epigastric, 6; nocturnal attacks, 8. Electrocardiograms were made in 57 cases of this series. The chief abnormality is a negative T-wave, which was present in 32 cases; in lead I alone in 8 cases; in II only in 3 cases; in III alone in 12 cases; in leads I and II in 4 cases; in leads II and III in one case; in leads I and III in 4 cases; in lead I in 1 case, and in all leads in 1 case. There was a cove-shaped T-wave in 12 cases. The urinary observations in this group were unimportant. In the blood-nitrogen tests made, no marked changes were found.

Management of Coronary Thrombosis and Complications.—Brown says that during the acute attack two important features are observed: the terrific painful discomfort and the state of shock. How is the pain to be relieved? This is one condition in which very large doses of morphine are justified. The initial dose may be one-half grain (0.03 Gm.). The morphine not only aids in relieving the pain but also helps to produce mental and bodily rest. Glyceryl trinitrate may be tried but should not be used if the systolic blood pressure is 100 mm. or lower. Very occasionally light ether anesthesia may be justified to relieve the pain. Shock in coronary thrombosis is to be managed much the same as when found in other conditions, except that stimulation is to be avoided if the peripheral blood pressure is sufficient to maintain adequate circulation. A systolic blood pressure of 100 mm. of mercury is usually taken as a criterion of sufficiency. If the pulse is imperceptible, caffeine sodiobenzoate, from 0.5 to 1 Gm., may be given intravenously; or strophanthin, 1 mg., intravenously; or epinephrine, 0.5 cc., intramuscularly may be used. In general, intravenous therapy, such as fluids in large amounts, is to be avoided as a greatly increased volume of fluid injected directly into the blood stream may embarrass the circulation still further. The body should be kept warm by blankets, hot-water bottles, or other forms of local application. An important caution is to do nothing that will cause the patient any muscular exertion. The physician should refrain from elaborate examination, and visitors are to be restricted. After the patient has passed through the attack of pain and is fairly comfortable, absolute bed rest still is imperative. He should remain as quiet as possible for several days. The continued use of morphine may be justified for several days; however, in many instances the common sedatives, such as bromide or phenobarbital may suffice. He should be spared the effort of feeding himself for the period of three days to one week. He should not have to use the bed pan more than once daily; slight constipation is a desirable occurrence during the first few days. The patient should remain at rest in bed for at least one month, and preferably for from six to eight weeks. Under no circumstances should he be allowed to get up before the end of one month. Rupture of the heart may happen up to the end of the second week or even later after the onset. During the period of recovery little in the way of treatment, other than that described, is necessary unless complications arise.

Hormone Influence in Rickets.—Kay et al. report that rachitic rats kept on a rachitogenic diet to which only thyroid gland has been added show healing by the line test. The dose of thyroid for rats seems fairly well established. The "hormone" seems to have a curative effect in rickets.

Treatment of Hay-Fever by Anterior Ethmoidal Injection.—Byrd points out that, as compared with immunization methods, the injection of the anterior ethmoid nerves for hay-fever appears to have the following advantages: It is as applicable after the onset as before, it eliminates the allergic tests for the offending pollen, it involves little loss of time for the patient and much conservation of energy for the physician, it eliminates the unhappy reactions occasionally encountered in desensitization, it yields a larger percentage of positive results, and, finally, it is applicable to seasonal and nonseasonal types alike. The foregoing considerations would seem to make injection of the anterior ethmoidal nerves the procedure of choice in the treatment of hay-fever. It is perhaps the only procedure applicable with marked success to those cases of hay-fever in which desensitization fails, while well nigh the only procedure applicable with any considerable success to the other disorders mentioned under such terms as vasomotor rhinitis, hyperesthetic rhinitis and nasal hydrorrhea.

Acute Empyema.—Locke has studied 478 cases to determine any relation that may exist between the type organism and the nature and course of the disease. The overwhelming majority of cases were secondary to pneumonia. The organisms most commonly found in the pleural exudate in empyema are the pneumococcus, *Streptococcus hemolyticus*, nonhemolytic streptococcus and *Staphylococcus aureus*. The general incidence of the pneumococcus and hemolytic streptococcus in the entire group of empyemas is 58 and 18.4 per cent, respectively, or 76.4 per cent if combined. Among the 417 cases with known bacteriology, 89.4 per cent were due to these two organisms. The incidence of the nonhemolytic streptococcus is 3.9 per cent, the staphylococcus 5.2 per cent, mixed infection and unknown 6.6 per cent and pus sterile 7.9 per cent. The overwhelming importance of the pneumococcus type I infection is evident from the fact that it constitutes 48.4 per cent of the total 417 cases of known bacteriology and 73 per cent of the 277 cases of pneumococcus infection. Types II, III and IV show an incidence in the whole series of 5.2, 2.7 and 7.9 per cent, respectively, indicating an insignificant position etiologically and in this respect comparable to the staphylococcus and the nonhemolytic streptococcus. The relation between age and the incidence of empyema is an important one. One third of all cases occurred in children under 10 years of age and 76 per cent in individuals under 40. Pneumococcus type I is the organism of the young, as in pneumonia. The average age of all patients with type I infection was 19. Type III, on the other hand, is the organism of older people, the average age in all typical cases being 45 years. Type II occurs in individuals of average age midway between types I and III; namely, 38 years. the type IV series shows an average age of 28 years. Blood cultures were made in 185 cases and found positive in one third. In general, bacteremia seems to be of much less prognostic significance in empyema than in pneumonia. The mortality was twice as great in the positive cases as in the negative, but even then only slightly above the death rate for all empyemas. There is no evidence that cases of empyema die of septicemia. Complications are common in empyema (265 in 478 cases) and are chiefly focal infections. Type I pneumococcus infections are especially prone to complications. The death rate with respect to the various organisms found in the empyema fluid is as follows: pneumococcus type I, 11.3 per cent; type II, 36 per cent; type III, 38.5 per cent; type IV, 29.7 per cent; all forms of pneumococci, 17.5 per cent; hemolytic streptococcus, 34 per cent; nonhemolytic streptococcus, 5.2 per cent; staphylococcus, 20.7 per cent; and finally for the total of 478 cases, 23 per cent. The death rate in the group of 416 cases treated by permanent drainage is as follows: pneumococcus type I, 9.8 per cent; pneumococcus type II, 21.0 per cent; type III, 20 per cent; type IV, 22.6 per cent; undetermined, 14.3 per cent; hemolytic streptococcus, 23.7 per cent; nonhemolytic streptococcus, 0.0 per cent; *Staphylococcus aureus*, 13.0 per cent, undetermined, 29.3 per cent; and finally for the total of 416 cases, 15.9 per cent. Age seems to play an important part in the mortality of empyema. In infancy the death rate is high, falling abruptly after the fifth year, but after this period the older the age groups, the higher the death rate. This increase in death rate with each decade is, however, considerably less striking and constant than in pneumonia.

Abnormal Labor as Etiologic Factor in Mental Deficiency.—Dayton outlines the Massachusetts system for the psychiatric examination of retarded school children, which has been in operation since 1915. A total of 43,975 examinations has been completed by fifteen of these traveling psychiatric school clinics. The Fernald ten-point scale examination is used. A total of 20,473 consecutive first examinations completed by six of the traveling clinics has been studied with the purpose of determining whether there is a relationship between abnormal labor conditions and various characteristics of the child. The study reveals that abnormal labor is in association with various mental, physical and emotional characteristics of retarded school children, apparently irrespective of the intelligence of the children involved. Whatever effect birth trauma may have on the various factors studied, it appears to exert this influence impartially on the two groups, whether mentally defective or not mentally defective. The results render imperative immediate study of the demonstrated association between abnormal labor and children in the higher intelligence groupings; that is, those in the dull normal or low normal classifications. They also point out the great need for additional study of the newly demonstrated relationships between abnormal labor and physical and emotional factors. These may prove to be of more vital importance than the association between abnormal labor and certain grades of intelligence.

Rupture of Spleen: Twenty-Seven Cases. L. Dretzka, Detroit.—p. 258.

Acute Pancreatitis.—According to Eliason and North, acute pancreatitis is not an extreme rarity and is entitled to more serious consideration than is customarily accorded it. The etiology is not understood, although considerable experimental data have accumulated. Cholecystitis is certainly a prominent factor. The correct diagnosis was made before operation in not more than one third of the cases reported in the literature. The character of the pain and the appearance of cyanosis are the most distinctive of the diagnostic criteria. The mortality in all the collected cases is 51 per cent. The accepted mode of treatment by emergency laparotomy may not be the best one. Experience favors dealing with these cases as one would with an uncomplicated acute cholecystitis or an acute salpingitis; namely, deferring the operation until after the acute phase, unless an occasion arises demanding immediate surgical intervention. A train of distinctive complications, for the most part incident to operative intervention, increases the hazard of early operation.

Obstetric Analgesia.—The formula used in more than 20,000 cases of obstetrics according to Gwathmey consists of: quinine alkaloid, 20 grains; alcohol, 40 minims; ether, 2½ ounces; liquid petrolatum or olive oil, sufficient to make 4 ounces. The final technic involves (1) three intramuscular injections of magnesium sulphate, each of 2 cc. of a 50 per cent solution; (2) an injection of morphine sulphate, ¼ grain, given with the first injection of magnesium sulphate only; (3) a rectal instillation of the foregoing formula. The medication varies in its results from a slight sedative effect to analgesia with unconsciousness, and amnesia. The progress of labor is not delayed. Occipitoposterior positions rotate in about the same proportion as in normal labor. Postpartum hemorrhage is less than with any inhalation method. If anything, the use of forceps is decreased, and the baby, as a rule, is born crying. Morbidity of the mother is decreased, and no fetal deaths attributable to the analgesia have occurred. Certain patients do well with the intramuscular injections of magnesium sulphate alone, or with the rectal instillation alone, but the best results are obtained when the full technic is used. When the patients come in with the cervix four fingers dilated, they are relieved considerably of pain with the intramuscular injections of magnesium sulphate, with or without morphine. There need be no fear in using the technic in cases of contracted pelvis or disproportion between baby and pelvis when a trial labor is indicated, for many will deliver normally. If they do not deliver, they have a great deal more reserve strength with which to withstand a hard forceps delivery or cesarean section. Patients who go through labor with the synergists have less postpartum fatigue and consequently less morbidity. They feel better and insist on getting out of bed early.

Useful Semianesthesia from Phenobarbital.—A surgical anesthesia produced by phenobarbital and nitrous oxide gas (at times ethylene) has impressed the Bartletts with certain definite advantages. There are no harmful preoperative anticipations. During the operation a surprisingly small quantity and concentration of gas has been required for complete satisfaction; consequently, cyanosis and bleeding are diminished, while hemostasis assumes a new and unwonted facility. After operation, one sees practically no sweating and comparatively rarely any nausea. The postoperative administration of fluids by mouth has in consequence largely supplanted the hypodermic and intravenous methods. There is, too, a welcome postoperative oblivion of many hours' duration (fifty-six hours in one instance). It is unusual for the patient to recall any incident from the day of operation. Phenobarbital alone makes the ideal preparatory drug in doses of from 12 to 30 grains (0.8 to 2 Gm.), given three hours before operation; it is rarely vomited; and no "supplementary" is needed as a rule. The dose, from 12 to 30 grains, has not harmed any adult, while 30 grains controlled perfectly the wildest toxic thyroid patient imaginable, who had entered the hospital only ten days before operation, with a basal metabolism rate of + 122.

Congenital Dislocation of Hip.—Soutter describes his operation as follows: An incision is made from the anterior superior spine of the ilium to 2 cm. below the top of the trochanter and then backward and upward. The soft parts are reflected upward, thus exposing the capsule of the joint; a slot is made through the outer and inner table of the ilium just above the head of the femur and extending some distance posteriorly and anteriorly. This slot is cut with an osteotome and is made sufficiently broad and long to hold a good size piece of bone. A square is cut from the outer table of the ilium above this and separated from the ilium at its lower edge and at its sides, while the upper edge remains in contact with the ilium. A graft is taken from a portion of the trochanter and the adjoining neck and shaft of the femur posteriorly (or anteriorly) and cut thick and large enough to cover a wide space above the head of the femur. This method of securing the graft simplifies the operation and eliminates the necessity of making a separate incision to obtain the graft. The graft is driven into the ilium. The square piece of bone, which was cut from the outer table of the ilium above the acetabulum, is lowered and remains in contact with the ilium at its upper edge. Its lower edge is fastened to the outer edge of the femoral graft with one catgut suture. The soft tissues hold this in place as they are firmly sutured over it. Its upper edge may be shortened in the middle, making this piece of bone longer at the sides than in the middle. These longer sides can be fitted into slots in the ilium, if necessary.

Diagnosis of Brain Abscess.—The case reported by O'Shea shows that an intracranial condition may coexist with chronic mastoid disease and cause few or no symptoms. The patient had chronic suppuration in a dense acellular mastoid with a minute antrum. Instead of draining, as it normally should, into the tympanic cavity and thence through a perforation in the drum (which it eventually did, but too late), it burrowed its way gradually through the tegmen and dura, forming adhesions in its course, into the temporal lobe, there forming a small chronic abscess. Ultimately, for some unknown reason, an acute otitis media arose, and the pus under pressure caused a perforation of the membrana tympani but spent most of its energy intracranially. Rupture of the abscess occurred, with subsequent meningitis. Nobody had ever heard the patient complain of ear trouble; it was said that she always seemed very healthy and enjoyed life. The appearance of the drum membrane on examination would seem to bear out this history.

Treatment of Bone Tuberculosis by Vitamins A and D.—Pattison used two preparations. One gave 150 blue with the antimony trichloride test, and has about twenty times the vitamin A potency of cod liver oil. It also contained 10,000 antirachitic units per cubic centimeter. The other had double the vitamin A content of preparation 1 (that is, 300 blue), but only 100 antirachitic units per cubic centimeter. Forty-three patients were given large doses of these preparations while thirty-five patients were given 10 cc. of cod liver oil daily. The latter were intended to act as controls and were selected because they had degrees of infection and bone invasion similar to certain patients in the other group of cases. The patients included in these tests were of varying ages—from 3 to 15 years—and in both groups there were cases with early disease, with acute rapidly progressing disease, with chronic slowly increasing disease, and with disease in which recalcification of bone was commencing. Of the forty-three patients, fifteen were given an average dose of 7.8 cc. of preparation 1 daily for an average period of 3.5 months, and were then given an average dose of 9.4 cc. of preparation 2 for a further average period of 3.4 months. The remaining twenty-eight patients were given an average dose of 9.6 cc. of preparation 2 for an average period of 4.1 months. The thirty-five control patients were given 10 cc. of cod liver oil daily during the period of investigation. All the patients, including the controls, got a fair supply of vitamin A and D, but those receiving the special vitamin preparations 1 and 2 had much more vitamin A than the others. Of the forty-three patients having the vitamin preparations, thirty-two were improved clinically and eleven were not; in twenty-five of these forty-three cases the roentgen rays showed arrest of disease or increased calcification, while in eighteen there was no evidence of such improvement. Of the thirty-five patients taking cod liver oil, twenty-five were clinically improved and ten were not. The roentgenograms of eighteen of these thirty-five indicated progress toward cure, while those of seventeen did not. Therefore, for the types of patients described, and with the dosages and under the other conditions mentioned, the use of preparations containing large amounts of vitamins A and D does not appear to be of more curative value than that of cod liver oil.

Combined Degeneration of Cord in Primary Anemia of Fowl: Its Pathogenesis and That of Associated Lesions.—In seven fowls, lesions of the cord, indistinguishable from those described as occurring in subacute combined degeneration of the cord in human beings, have been found by McGowan. In all the cases this has been associated with the existence of a high degree of hemosiderosis of the liver, spleen and kidney, and also of the mucosa of the duodenum, when this was examined. In three cases there was also marked sclerosis of the bones, with great diminution in the quantity and marked change in the appearance of the marrow. The marrow, when examined microscopically, has been found to be abnormal in all the cases. In some it showed atrophy or aplasia; in others, considerable diminution, accompanied by great increase and distention of the venous sinuses; while in others it showed a hemocytoblastic hypertrophy, such as one finds typically in active pernicious anemia of the fowl. In some of the cases there was comparatively little alteration in the circulating blood. In one case, however, there was considerable reduction in the hemoglobin percentage and number of red blood cells, while in others there was evidence of blood instability, as shown by the presence of erythroblasts. McGowan concludes that pernicious anemia is the involvement of the bone marrow in an irritative process which causes it to revert to embryonic cell formation. The resulting anoxemia causes, secondarily, the complications to be found in the central nervous system, the stomach and the liver (later stages). There is no evidence for the existence of a "pernicious anemia diathesis" in relation either to the disease as a whole or to the organ complications.

Thoracic Stomachs.—Theories are mentioned by Adams which encourage the belief that there is defective neuromuscular action at the esophageal exit, but whether this is inherited, brought on by the irritation of imprudent feeding, reflex from distant foci of disease, or the result of local neural degeneration, further research must prove. It is probable, he says, that a neuromuscular dysfunction at susceptible transition points in the gullet raises the pressure of ingesta. This effect expresses itself by different forms of dilatations. The inherent weakness in the posterior aspect of the hypopharynx produces a hernia of the mucosa. By contrast, in the epiphrenic region, the esophageal walls respond to the hypertension within by a typical uniform dilatation and hypertrophy. From such origins spring the substernal and epiphrenic stomachs. They are likely to continue to vex the human race, evoke the discernment of the physician, elude prophylaxis, and require most skilful surgery to relieve them. In pharyngeal pouch, two-stage diverticulectomy is the best remedy, while cardiospasm in the early stages will respond to mere dilation with bougies, which is best done with the aid of the radiographic screen. Where this fails, Mikulicz's digital dilation, by means of a gastrotomy, is necessary and effective. By reason of the comparative infrequency of these conditions, their deep situation and the vital structures around them, their treatment calls for special care and skill.

Spontaneous Subarachnoid Hemorrhage, with Korsakoff's Psychosis.—Cubitt cites the case of a man, aged 57, who had recurrent subarachnoid hemorrhages, and from each succeeding hemorrhage the recovery was less complete. He developed Korsakoff's psychosis, and finally died seven days after the first hemorrhage. The diagnosis was confirmed at necropsy. The sudden appearance of pupillary and pyramidal tract signs with each fresh hemorrhage, and their rapid disappearance after the relief of pressure by lumbar puncture, was an interesting feature of the case.

Short Study of Nephritis in Children.—The glomerular type of nephritis preponderated in twenty-two of the thirty-six cases falling into this category reviewed by Guthrie. A striking feature of the acute glomerular lesions is the relatively slight degree of pathologic change demonstrable, death having taken place in some cases in which the only glomerular lesion present was acute congestion of the capillaries. It is also of interest that the majority of cases of glomerular nephritis gave no history of previous acute illness to which the inflammatory renal condition might be attributed. In the more chronic cases, naked-eye examination failed to give any indication of the degree of the histologic changes present. The cases with marked chronic tubular lesions were apparently from the histologic *changes in the glomeruli, of an inflammatory,* rather than of a degenerative, nature. From a general survey of these thirty-six cases of nephritis in children, it would appear that classification on naked-eye examination is more difficult than in adults, and that in most cases a definite diagnosis of the type of renal lesion present is not possible without microscopic examination.

Action of Opium and Narcotine in Malaria.—Experiments made by Chopra and Knowles failed to elicit any evidence to show that opium has any prophylactic or curative effect in malaria. The alkaloid narcotine even in such large doses as 10 to 15 grains (0.65 to 1 Gm.) daily had no effect on the parasites of any forms of malaria circulating in the peripheral blood. The temperature of the patient remained unaffected and rigors and paroxysms continued.

Action of Opium in Diabetes.—By the administration of small doses of opium, from 1 to 6 grains (0.065 to 0.4 Gm.) daily, Chopra and Bose effected a slight reduction in the total quantity of urine excreted in mild cases of diabetes. In severe cases it did not reduce polyuria, thirst or frequency of micturition. In the early and mild cases of diabetes, opium had a well marked effect in reducing the total daily output of sugar in the urine. In some cases the sugar entirely disappeared from the urine under its influence. In severe cases of diabetes, however, it had no effect on the sugar output. Opium had not much effect in reducing the amount of blood sugar of diabetic patients; in fact, in severe forms of the disease it actually increased it. In some patients the administration of opium distinctly raised the renal threshold for excretion of sugar. The sugar in the urine disappeared while that in the blood was increased. It would not, therefore, be advisable to use opium in this disease.

Pharmacologic Action and Therapeutic Uses of Narcotine.—Experimental evidence is produced by Chopra et al. in support of the view that narcotine, unlike morphine, stimulated the respiratory center in the medulla. The plain muscles of the bronchioles are relaxed. The drug, in animals at any rate, has a stronger action on the cord than on the brain. Narcotine has a depressant action on the algesic areas in the brain and therefore lessens such symptoms as headache, pain in the limbs, and discomfort, attendant on febrile conditions. It undoubtedly potentiates the action of morphine and codeine so that much smaller quantities of these alkaloids would be effective if given in combination with narcotine. The voluntary muscles are not affected. It is stated that the alkaloid could be employed in medicine for its synergistic effects on the sedative properties of morphine, codeine and diacetylmorphine. By iself it is beneficial in allaying cough, headache and other minor conditions producing pain of a milder type. On account of its depressant action on the involuntary muscle tissue it would be useful in such conditions as asthma, whooping cough, and spasm of muscular tubes such as the intestine, bile duct and urethra.

Pathology of Chronic Colitis in Tropics.—The different types of dysenteric lesions are described by Menon from a study of material and records from 800 necropsies. He asserts that about 60 per cent of fatal cases of "chronic" colitis or "chronic diarrhea" of indefinite origin show morphologically strong resemblance to the lesions of chronic dysentery. Some cases show an atrophied state of all the coats of the large and small intestine, the exact cause of which has not been determined.

Rôle of Urinary Colloids in Prevention of Stone Formation.—Against the arguments for the theory that the urinary colloids are the mechanism by which certain difficultly soluble constituents of the urine are prevented from precipitating, the experiments made by Newcomb have shown that other colloids (starch, gelatin, serum, albumin and milk) have no effect on the solubility of such constituents (uric acid, oxalates and phosphates) in an artificial mixture of salts resembling urine. On the dialysis of normal urine the uric acid distributed itself evenly on both sides of the dialysis membrane. This shows that the uric acid is not firmly attached to the colloids. If normal urine was dialyzed and the dialysate evaporated to the concentration of the original urine, no precipitation occurred *if the acidity was kept at, or restored to, its original value.* A clear solution of all the crystalloids (including the uric acid, oxalates and phosphates) in their original concentrations could be obtained in the absence of colloids, so long as the acidity was kept the same. Newcomb feels that, while normal urine undoubtedly contains colloids, it is doubtful whether these have any considerable influence on the precipitation of such constituents as ordinarily go to form urinary calculi.

Pernicious Anemia of Pregnancy.—It is suggested by Wills and Talpade that a relative deficiency in vitamins A and C or some factor associated with this deficiency is concerned in the etiology of "pernicious anemia of pregnancy," and that the proportion of fat and vitamin B in the diet may play some part in determining the incidence of this disease in a population generally short of vitamins A and C.

*Paratherapeutic Icterus: Diagnostic Value of Cholesteremia Level. M. Vauthey.—p. 481.
*Familial Hypotrichosis Due to Endocrine Disturbances Caused by Congenital Syphilis. H. Behdjet.—p. 493.

Paratherapeutic Icterus: Diagnostic Value of Cholesteremia Level.—In the pathogenesis of paratherapeutic jaundice the state of tolerance or of intolerance of the liver and its susceptibility play an important rôle, which should not be overlooked in the general tendency to ascribe to the disease a toxic or a syphilitic origin. Insisting on the importance of a prior hepatic terrain, Vauthey names three factors concerned in the development of jaundice following antisyphilitic chemotherapy: ordinary hepatic presensitization (through alcoholism, gallstones, malaria or tuberculosis); a specific hepatic presensitization due to spirochetes or their toxins, and the action of chemical medicaments. The author then distinguishes two types of paratherapeutic jaundice: (1) cases of syphilomedicinal origin and (2) those of a purely medicinal source. Diagnosis should be based on three criteria considered simultaneously. These are the hepatic antecedents, the intensity of the syphilitic manifestations, and the cholesteremia level. If this level is below normal in the course of paratherapeutic jaundice at the end of the first or in the second period, associated with syphilitic manifestations but without commonplace hepatic antecedents, the jaundice is probably of syphilitic—that is, syphilomedicinal origin. If the level is above normal in the same conditions of evolution of syphilitic infection, but in the absence of manifestations of syphilitic activity, and with evidence of hepatic presensitization, a purely medicinal icterus may be diagnosed. The treatment for the latter form calls for absolute suppression of the medicine linked with the appearance of the disease. Arsenic compounds should be replaced by bismuth salts or mercuric cyanide.

Familial Hypotrichosis Due to Endocrine Disturbances Caused by Congenital Syphilis.—Behdjet reports two cases of this disorder occurring in three generations and among members of one family, and in two generations in the second family. In addition to alterations in the internal secretion glands there existed also other symptoms of congenital syphilis.

Archives des Maladies de l'App. Digestif, etc., Paris

20: 641-760 (June) 1930

*Gastric Pain in Functional Dyspepsias. P. Oury, P. Godard and V. Nichita.—p. 641.
*Syphilitic Celialgia. J. Turriès.—p. 660.
Tetanus in Amebic Dysentery: Case. C. Farmakidis.—p. 669.

Gastric Pain in Functional Dyspepsias.—A comparison between the clinical, roentgenoscopic and chemical examinations of patients with stomach pains and disorders was made by Oury et al. to determine in what measure gastric pain corresponds with variations in the form and chemistry of the stomach. About sixty patients whose troubles could be diagnosed as functional dyspepsia were divided into four groups: (1) hypochlorhydria with normal or exaggerated tonicity; (2) hyperchlorhydria with hypotonia and feeble or no kinesia; (3) anachlorhydria or hypochlorhydria with orthotony, or normal or exaggerated kinesia; (4) simple hypokinetic ptosis with subnormal chlorhydria. The results of their study showed that the division of gastric pains into burning, cramps, twitching, heaviness and so on did not correspond to any precise clinical type. Often the classic types of hypersthenia and hyposthenia did not correspond to anything definite. Phenomena of antiperistalsis as well as alkaline regurgitation from the duodenum played an important part in the establishment of the chemical composition of the gastric sugars examined, and in various dynamic and static disorders. Contrary to expectations, the largest group was not found to answer the definition in group 4, from which the authors concluded that patients with simple ptosis suffer from this disorder only when the ptosis is complicated by secondary disturbances. Finally, the largest number of patients with gastric pains was found to be those with hyperchlorhydria.

Syphilitic Celialgia.—The syphilitic origin of attacks of severe pain in the epigastric region is the subject of the investigations of Turriès. In such cases, the symptoms are cramps, sensations of twisting, burning or of heaviness, often localized in the epigastric region and in general, without notable irradiation except toward the vertebral region. The pain element is not constant but has an alternating or undulating rather than a periodic evolution. Vomiting, hematemesis or nausea is not observed. Salivation is sometimes noted, also slight constipation. The most constant symptom is pain revealed on even slight pressure over the solar plexus. The general condition of the patient is satisfactory; a slight asthenia with irritability, and sometimes insomnia are also symptomatic. Although such cases have usually been variously diagnosed, the author finds that a complete detailed study will reveal in addition to the painful epigastric syndrome two others; namely, manifestations of (1) syphilitic infection, and (2) sympathetic dystonia. In the latter instance, the most common signs of vagosympathetic disequilibrium to be found are vasomotor (emotional and postprandial) disturbances and cenesthesic disorders. As to the syphilitic element, it is rarely great. Spirochetal infection, often latent or disguised, is revealed by various signs, such as anisocoria, inexplicable, long standing refractory encephalitis, and modified reflexes. To prove that the disorders were of the etiology suspected, the author applied therapeutic tests. All digestive as well as the customary sedative treatments failed, while in all the cases considered in this present study only spirocheticidal treatment gave certain and lasting results.

5: 93-194, 1930

*New Method of Auscultation. F. Parodi.—p. 93.
Roentgen Changes Simulating Hemithoracic Stricture with Superelevation of Hemidiaphragm Due to Pulmonary Sclerosis and in Reality Due to Pulmonary Atelectasis and Paralysis of Phrenic Nerve. E. Sergent and J. Vibert.—p. 116.
Syphilitic Pulmonary Granuloma. J. Dechaume.—p. 127.
Hemoptysis and Meteorological Conditions. J. Chaize.—p. 155.

New Method of Auscultation.—In an analysis of the physical and physiopathologic principles of the most important signs in thoracic auscultation, Parodi notes that vesicular respiration and bronchial respiration are physical entities separated by their origin and their acoustic character. The bronchial bruit is determined by the vibration of air on the vocal cords and in the bronchial tubes, and vesicular respiration by the vibrations of the pulmonary parenchyma during respiratory distention. The height and intensity of the sound perceived on the periphery are relative to the homogeneity and density of the interposed parenchyma. The more dense and thick the tissue that unites the bronchial tubes to the thoracic wall, the higher and louder is the sound. Râles are always formed in the area of greatest stricture in the bronchial tubes. Their tonality is determined by particular pathologic conditions that provoke an increase in the speed of the current of air in the tubes. The tonality is relative to the conditions of the surrounding parenchyma. Each time the sound extends beyond its center of origin, an anatomic alteration of the bronchial or vesicular system is to be inferred. Hence any variation in the depth of physiologic respiration indicates a pathologic alteration. The difficulty in auscultation lies in the distinction of the high or pathologic sounds from the low or physiologic sounds. In order to distinguish these two, to eliminate the low sounds, and to bring in the high sounds perceived on the periphery of the thorax, the author has devised an instrument, which he terms a "phonoselectoscope," constructed according to the principles of modern acoustics. Not only does the use of such an instrument as the one described by the author facilitate the distinction between pathologic and physiologic signs, thus rendering an easier, earlier and more exact diagnosis of pulmonary diseases, but it also furthers a deeper study of problems in pulmonary and cardiac auscultation. Moreover, it facilitates the teaching of auscultation technic, by means of a scientific method, and permits provision for the nomenclature of pulmonary symptomatology as well as the possibility of simplifying it by correcting faults that are at present regarded as classic notions.

Chronic Nephritis and Facial Paralysis.—Vinard and Puech report a case of chronic, hypertensive albuminous nephritis with edema and azotemia, and hemorrhage in the petrous canal of the facial nerve, causing facial paralysis. The patient's clinical history revealed a tendency to hemorrhages. Lesions of the kidneys and liver predisposed the patient to such conditions. It is the opinion of the authors that facial paralysis in chronic nephritis is caused not by a primary or a superadded infection but by a local hemorrhage due to vascular rupture analogous to that frequently seen at the level of the nasal fossae, the retina or the brain.

Pernicious Anemia Treated with Preparations of Desiccated Stomach.—Relative to the treatment of pernicious anemia, Lambin and Steenhoudt describe preliminary experiments made with a powdered mucous membrane of hog stomach, and another powder of the dried muscular tissue of the stomach. From their observations they conclude that (1) administered on a meatless diet, the dried gastric mucosa showed only a relatively small activity; (2) ingested together with 200 Gm. of beefsteak, the same quantity of the mucosa powder produced results approximately three times as great; (3) the powdered muscular tissue did not assure continuation of the abatement of the symptoms of the disease.

Blood Chlorine and Its Distribution in Plasma and Erythrocytes: Therapeutic Indications.—The choice of a serum may become problematic when a selection is urgent in order to check a nursling's rapid loss of weight, owing to various causes. Blood examination will give the necessary indications through the determination of the chlorine content in the erythrocytes and the plasma. From this, Ribadeau-Dumas et al. deduce two facts that bear on the application of their special therapy: (1) the absolute value of the amount of the blood chlorine; (2) the distribution of chlorine in the plasma and erythrocytes expressed by a ratio of about 0.48. In cases in which the ratio is found to be above normal, the authors advise ingestion or injection of bicarbonated serum; in some cases a complementary serum is necessary, such as a serum treated with dextrose with or without insulin, or Ringer's solution. If the ratio is not modified but the absolute chlorine value is, an injection of serum treated with dextrose or insulin is required instead of a salt serum, since it is necessary to rehydrate the organism without effecting a new ionic surcharge. If the ratio is lowered, Ringer's solution should be injected. Guided by hematologic examinations, the authors have had excellent results from the use of this serum treatment.

Anterior Dislocation of Head of Fibula and Interstitial Emphysema of Calf of Leg in Open Fracture of Lower Third of Tibia. Botreau-Roussel and P. Huard.—p. 769.
Postoperative Cicatricial Stenosis of BBiliary Tract Following Retrograde Cholecystectomy: Case. B. Desplas, G. Durand and J. Meillère.—p. 773.
Gallstones and Chronic Pancreatitis: Case. B. Desplas, J. Dalsace and J. Meillère.—p. 776.
Traumatic Lesion of Radius: Case. A. Mouchet.—p. 782.

Volvulus of Intra-Articular Pedicled Lipoma of Knee: Case.—Diamant-Berger reports a case of the twisting of a pedicled intra-articular lipoma of the knee. The tumor was of traumatic origin. Prior to resection there had been severe pains and functional disturbances which in some measure simulated true articular blockage, yet no torsion of the pedicle had ever been indicated.

Total Volvulus of Small Intestine: Two Cases.—In two cases of total volvulus of the small intestine, the presence of lesions was indicated by an acute occlusion syndrome. Matry describes the symptoms, the diagnosis and the treatment by means of laparotomy and detorsion.

Perforation of Gallbladder in Severe Typhoid.—On the nineteenth day after the development of typhoid, a perforation of the gallbladder occurred in a patient, aged 11. Fèvre et al. advocate cholecystostomy under local anesthesia as the safest course in such circumstances.

Recurrence of Papilloma of Bladder. P. Bazy.—p. 806.
Phenyl Salicylate as Urinary Antiseptic. P. Bazy.—p. 814.

Duodenal Fistula Following Suture of Perforated Ulcer.—The treatment in this case of perforated ulcer of the duodenum consisted of suture of the perforation, gastro-enterostomy, and drainage of the perforation locale. But shortly afterward there appeared a fistula that was refractory to treatment. A second operation revealed at the seat of the fistula an extensive induration and marked stenosis of the duodenum. Moulonguet resected the whole anterior wall of the first portion of the duodenum, sutured the breach and reestablished the continuity and permeability of the duodenum.

Torsion of an Appendix Epiploica of Left Colon.—Such a torsion abruptly blocks the colon and brings about a decided reflex colic distention throughout, inhibiting peristalsis. In this case there were severe localized pains, with a temperature of 102.2 F. and an absence of abdominal rigidity. After administering a spinal anesthetic, Braine made an incision that revealed a violet-red appendix epiploica of the colon as large as a chestnut, twisted back on itself and attached to the colon only by a filiform pedicle twisted and on the point of becoming detached. The pedicle was sectioned and a drain inserted in the rectovesical pouch.

Persistence and Value of Antitoxic Immunity in Persons Vaccinated with Diphtheria Anatoxin. G. Ramon, R. Debré, M. and G. Mozer and G. Pichot.—p. 841.
*Albumins and Albumin Quotient of Serum in Pulmonary Tuberculosis. A. Dufourt, Robert and Moreau.—p. 843.
*Physiopathologic and Clinical Interpretation of Pirquet's Cutaneous Allergy in Pulmonary Tuberculosis. F. Parodi.—p. 845.

Albumin Quotient of Serum in Pulmonary Tuberculosis.—In their experiments, Dufourt et al. found that the normal albumin quotient in healthy persons varies from 1.6 to 2. They then examined the serum of twenty-four tuberculosis patients, mostly women, of whom the oldest was 46. The ten patients of the first group (only slightly tuberculous) showed practically a normal quotient: from 1.5 to 2.1. The eight patients of the second group (more seriously affected by tuberculosis) showed wholly conflicting results. Four of the third group of six patients considered clinically as incurable showed low quotients: from 0.6 to 1; the other two were normal. It is to be noted that the figures in the results do not always conform to the clinical examinations but in general a high quotient is a good indication, a low one unfavorable.

Interpretation of Pirquet's Cutaneous Allergy in Pulmonary Tuberculosis.—Parodi disagrees with the conception of the word allergy as used by Pirquet. He maintains that allergy is only the relative sensitization of certain nerve tracts and that the cutaneous reactions are neurotrophic reactions of reflex nature and of visceral origin. It is doubtful whether there exists a true hypersensibility of the organism to tuberculous toxins. In any case, Pirquet's allergy is not a humoral reaction nor does it belong among the immunity reactions.

38: 857-872 (June 25) 1930

*Acute Abdominal Syndrome of Physiologic Sections of Spinal Cord. A. Hamant, L. Cornil and M. Mosinger.—p. 857.
Tuberculosis and Internal Oxidations. P. Delore.—p. 861.
Alimentary Anaphylaxis and Peroral Desensitization by Besredka Method. R. Jahiel.—p. 866.

Acute Abdominal Syndrome of Physiologic Sections of Spinal Cord.—Hamant et al. call attention to visceral complications following spinal cord traumatism. Abdominal disorders in particular are noted. The lesions may be a wound, a complete section, or spinal cord concussion. In acute transverse myelitis, abdominal meteorism of sympathetic origin is frequent. Surgical operations on the spinal cord, which often give rise to postoperative pulmonary complications, likewise may result in paralytic ileus. Intestinal occlusion may follow sympathetic lumbar ramisection. Traumatisms of the sympathetic chain are also at times accompanied by paralytic ileus. Under clinical considerations the authors note that the first symptoms appear after a period of latency varying from two hours to two days but other authors have occasionally noted much longer delays. In general the syndrome is announced by meteorism. The functional signs vary and are sometimes lacking. The anal and vesical sphincters may show contracture. The temperature is variable; the pulse is usually more than 100; priapism occurs. Sympathetic extra-abdominal disorders are to be found. The authors distinguish between the benign and the malignant forms of the acute abdominal syndrome, describe the evolution of the two forms, and call attention to their association with pulmonary disorders. Necropsy shows decided congestion of the peritoneum and of the viscera. In general, the posttraumatic abdominal syndrome is characterized by (1) abdominal vasodilatation, varying in importance, which in serious forms is manifested by hematuria, hematemesis, melena, and hepatic congestion, (2) disturbances of intestinal motility, (3) gastric hypersecretion and renal dysfunction. Anatomicoclinical analogies follow between the abdominal syndrome of spinal cord section, of traumatic abdominal and of postoperative abdominal origin. In addition to the frequent occurrence of acute abdominal disorders resulting from traumatism of the spinal cord or acute transverse myelitis, the authors observe that they are characterized by abdominal vasomotor disturbances, by disturbances in the motility of the intestine, and by disorders of the digestive and urinary secretions. As to the pathogenesis, their anatomicopathologic verifications and study of the functioning of the peripheral sympathetic show that traumatic inhibition of the spinal cord centers (by its bringing about a real ramisection), as well as the ramisection operation, does not act as one might think by means of a local hyperparasympathetic effect or by one of purely sympathetic inhibition.

Revue Française de Pédiatrie, Paris

6: 137-264, 1930

Oscillations in Human Temperature. Michalowicz.—p. 137.
*Dietetic Treatment of Diarrhea in Nurslings. L. Moll.—p. 177.
*Antituberculosis Vaccinations by the Calmette Method. Prokopowicz-Wierzbowska.—p. 191.
Status Thymicolymphaticus in Children, Followed by Sudden Death. P. Gautier.—p. 213.
Organizations for Distribution of Mother's Milk. Maretzka.—p. 222.

Dietetic Treatment of Diarrhea in Nurslings.—It is essential to find a diet that, during the diarrhea, will give sufficient liquid with enough salt to permit a retention of water and provide enough calories to prevent inanition. The purpose of this "transition diet" is to arrest loss of weight, after which a diet is given to increase weight again. Moll finds that mother's milk is an excellent reparation diet but that it is not a satisfactory transition diet. For the latter he prefers a preparation of milk of almonds and whey. This is especially suited for younger nurslings. For those somewhat older the author prescribes a pudding made of a special flour with water, sugar, egg, salt and sodium carbonate. This is steamed, strained and diluted with tea, whey, milk of almonds or mother's milk. The almond milk diet is richer in calories and it can be given from four to five days, even for two weeks, without exposing the child to danger from the lack of protein or mineral substances. The average duration of this diet is one week, after which the child's ordinary diet may usually be resumed. The author gives recipes and formulas for his various diet preparations.

Antituberculosis Vaccinations by the Calmette Method.—From her experiments with B C G antituberculosis vaccinations, Prokopowicz-Wierzbowska found that the B C G vaccine had no ill effects on newly born children; also that exogenic agents, such as bad hygienic conditions, defective diet, contagious diseases and digestive or respiratory disorders, exerted no influence capable of increasing the virulence of the B C G stock and did not determine the appearance of tuberculosis in the child. Children thus vaccinated who lived in healthy surroundings did not develop tuberculosis. The vaccinations determined an allergy that was shown by the Pirquet reaction in children living in an atmosphere free from the taint of tuberculosis. Some of the vaccinated children who lived exposed to a contagious form of tuberculosis were infected (positive Pirquet reaction) but did not contract the disease. In rare and exceptional cases in which the children were not isolated after vaccination, early infection did result in severe forms of the disease. The author states finally that it is indispensable to isolate the children who are vaccinated, during the time specified by Calmette.

*Behavior of Eosinophils in Tuberculosis in Children. G. Belloni.—p. 371.
*Schilling's Hemogram in Normal Persons and in Persons with Pathologic *Conditions. I. Gazzotti.—p. 397.*
*Incoercible Vomiting in the New-Born: Congenital Atresia of Stomach. G. A. Piana.—p. 431.

Behavior of Eosinophils in Tuberculosis in Children.—Belloni studied the behavior of eosinophils in children with several forms of tuberculosis, before and after the application of antituberculosis treatment. The treatment comprised improvement of the hygienic and nutritional conditions of the children and tuberculinotherapy (both by cutaneous and by hypodermic routes). The author made observations in three groups of children: sixty children who had not received treatment; fifty who had been treated for some time, and twenty-six both before and after receiving treatment. In the last mentioned group, ten children had latent tuberculosis, ten had marked tracheobronchial adenopathy, four had pulmonary tuberculosis, and two had tuberculosis of the bones. The counting of the eosinophils at the second examination was made five months after the treatment had been received, and under the same conditions as it was made the first time. The author considers the results of the first and second groups in relation to those of the third group, before and after the treatment, respectively. The author concludes that in tuberculosis in children (with either a biologic or a clinical diagnosis) there exists a slight eosinophilia, which is related neither to the age or sex of the patient, nor to the localization of the tuberculous lesions. The eosinophilia coincides with an improvement of the patient's general condition in children who had not received treatment. In patients who have already received treatment, the increase of eosinophils is not an indication of the good general condition of the patient but is in relation to a greater positivity of the skin reaction. The several methods of tuberculinotherapy cause in the organism of the children an increase in the eosinophils. However, the behavior of the eosinophils cannot be accepted as having reliable diagnostic or prognostic value in tuberculosis in children.

Schilling's Hemogram in Normal Persons and in Persons with Pathologic Conditions.—Gazzotti studied the behavior of the neutrophil granulocytes in blood pictures made according to Schilling's method, in ten persons (five of them aged more than 70 years) and in forty-three persons with the following diseases: typhus, paratyphoid, undulant fever, influenza, serous peritonitis, pneumonia, exudative pleuritis, grave septicemia, purulent pleuritis, strangulation of the hernial sac, and acute appendicitis. The figures of the blood picture appear in several tables. The author's results in normal persons were similar to those published by Schilling. The dissimilarity observed in the figures given by patients beyond 70 years may be considered as a manifestation of the changed conditions of the functions of the several organic systems in senility. The figures of the blood pictures made by the author in persons with pathologic conditions agree with those published by Schilling. The neutrophils varied with the severity of the disease. The author considers, however, that the method of examination of the blood proposed by Schilling does not have by itself sufficient diagnostic or prognostic value to replace the ordinary clinical and laboratory methods. It may be a useful (though by no means indispensable) coadjuvant method in the diagnosis and prognosis of several pathologic conditions mentioned which the author observed.

Incoercible Vomiting in the New-Born: Congenital Atresia of Stomach. — Piana reports a case of congenital atresia of the stomach in a new-born infant at full term. The infant was born in a condition of general denutrition. He had incoercible vomiting after receiving even the smallest amount of liquids. The vomiting was of a regurgitant type and the liquids were vomited without showing any modification. The child had also constipation. Feeding was impossible. The patient lost weight rapidly, going down from 1,850 Gm. at birth to 1,250 Gm. six days later. A Nélaton catheter could be introduced no farther than the cardia. The introduction of air through the catheter failed to cause any distention in the epigastric region. The infant died on the sixth day. At necropsy it was found that the capacity of the child's stomach was only 4 cc. and that it had rigid and thick walls. The mucous membranes were atrophic. The development of the muscularis mucosae was deficient in regard to normal but excessive with regard to the volume of the organ. The author considers that the atresia of the stomach in this infant had originated during the early intra-uterine life. The presence of lesions of endarteritic proliferation in the stomach, in the pancreas and in the liver found at necropsy, as well as the tendency to the development of sclerosis in some other organs, indicated that the lesion had a vascular origin caused by the influence of a toxic and infectious factor, probably syphilis. (In this case the father was unknown and the Wassermann reaction was not made in the mother or in the infant.) The author says that syphilis may be considered as the causal factor in some cases of incoercible vomiting in infants.

*Total Nitrogen Content of Blood, Urine and Feces in Child, Considered in *Relation to Various Types of Feeding.* A. Simonini.—*p.* 487.
Adiposogenital Dystrophy. I. Soriani.—p. 515.

Bactericidal and Therapeutic Property of Tin Compounds.—Valentini concludes from his experiments that the opportunities to employ preparations of tin are few, owing to the difficult solubility of its compounds. Secondly, preparations of tin have a weak antiseptic potency toward bacteria in general and an especially weak potency toward staphylococci, so that their use in disorders caused by such bacteria appears to the author of doubtful value. The uselessness of preparations of tin in the treatment of tuberculosis (human and bovine) appears evident from this research. As regards the tolerance of the tissues toward injections of preparations of tin in the strengths that he employed, the author thinks it was always rather good.

Nitrogen Content of Blood, Urine and Feces in Child, in Relation to Types of Feeding.—Simonini studied the nitrogen metabolism in children on various kinds of diet. He concludes that the nitrogen content of breast-fed children tends to increase as the child grows older but does not ordinarily exceed a certain physiologic limit. As for the children artificially fed, the author noted an excessive increase in the nitrogen content. *Such increase explains* why in those children intoxications, dyspepsia and gastro-enteritis due to proteins develop so easily. In children of the third group who have completed the first year of life, the mixed diet is well adapted to their existence, because the nitrogen content is approximately that of breast-fed children.

*Rare Syndromes of Intestinal Parasitosis. G. Ranieri.—p. 839.
Psychic Variations in Persons Suffering Injuries of Cranium and Spinal Column. F. Allodi.—p. 840.

Rare Syndromes of Intestinal Parasitosis. — Ranieri describes a case of spastic intestinal pseudo-occlusion due to helminthiasis (ascarids and oxyurids). The patient, a boy aged 15, had been admitted to the hospital with a diagnosis of intestinal occlusion, and an emergency operation was contemplated. The patient presented all the symptoms of an acute abdominal syndrome, but some signs (absence of profound asthenia and of cardiac adynamia; subfebrile temperature, vomiting becoming less frequent) pointed to pseudo-occlusion. A number of enemas evacuated old feces with many ova of *Ascaris lumbricoides, Oxyuris vermicularis* and *Trichocephalus dispar.* A purge cathartic eliminated a few ascarids. Recovery followed.

Ethylhydrocupreine Hydrochloride in Treatment of Pleurisy in Infants.—Acuña et al. treated four infants, aged from 10 to 30 months, who had purulent pleurisy, by means of evacuant tappings, followed by lavage of the pleural cavity with a 5 per cent solution of ethylhydrocupreine hydrochloride, and intrapleural injections of either a 2 per cent or a 5 per cent solution of the same drug. It is claimed that the drug has an elective antiseptic action on the streptococcus in vitro. With the tappings, quantities of pus, laden with pneumococci (only in one of the cases was it laden with streptococci) were removed. In two cases complete recovery was not obtained with the treatment alone, though the patients' general condition improved. In the two cases the performance of a pleurotomy with costal resection was necessary after some tappings. The other two infants obtained complete recovery only from the evacuant ethylhydrocupreine treatment. In the last mentioned two infants the end of the pleural process was characterized by the transformation of the scanty remaining intrapleural fluid, into a sterile, hemorrhagic and gelatinous exudate. In pleurisy in early infancy (which the authors consider a serious condition) the treatment gives a high percentage of complete recoveries. It is also of value in the cases of pleurisy in which an operation is contemplated. It improves the general condition of the patients, thus permitting one to defer the operation till its dangers are minimal.

New Reaction of Choline and Lecithin. — Sánchez explains the mechanism of a new reaction of choline which may be applied to its most important derivatives. The primary reaction consists in the transformation of the molecule of the nucleus of the choline into iodoform, by means of two reactives, iodine-iodide and sodium hydroxide. To apply the same reaction to lecithin, the following method is used: Ten cubic centimeters of a 5 per cent solution of sodium hydroxide and 0.1 Gm. of lecithin is boiled for five minutes. It is then cooled and a 0.5 per cent solution of sulphuric acid is added drop by drop till a complete acid reaction is obtained. This solution is filtered through a wet filter in order that the fatty acids may be separated. The filtrate contains choline, phosphoric acid and glycerin. With 1 cc. of this filtrate, Lieben's test or the iodoform test may be performed.

Accident in Swallowing Capsules of Tetiothalein Sodium.—Heuser's patient, aged 60, after having expelled some gallstones was told to swallow some capsules of tetiothalein sodium for roentgen examination of the gallbladder. When the capsules were swallowed, one of them was deviated. The patient complained for several days of ardor of the throat and difficulty in speaking. The laryngologist believed that the capsule had lodged in the trachea instead of passing into the esophagus. An examination of the larynx showed edema of the vocal cords but failed to show the presence of the foreign body. Roentgen examination showed a shadow from the fourth cervical vertebra to the insertion of the first rib, and then as far as the diaphragm. This shadow was observed behind the trachea, which outline was clearly manifested in front of the dark shadow. The patient recovered after several days. Roentgenography in this case had a double value, both from the point of view of the interpretation of the roentgenogram, and from the clinical point of view of the diagnosis.

Deutsche Zeitschrift für Chirurgie, Leipzig

224: 353-425 (July) 1930

Pyelovenous Reflux and Hydronephrosis. F. Fuchs.—p. 353.
*Treatment of Tuberculosis of Epididymis: End-Results. F. Felsenreich.—p. 383.
*Isolated Actinomycosis of Kidney Secondary to Empyema of Sphenoid Sinus. H. Recht.—p. 414.
*Primary Sarcoma of Seminal Vesicles with Multiple Brain Metastases and Two Cases of Carcinoma of Seminal Vesicles. H. Junghanns.—p. 418.
Primary Calculus Formation in Posttraumatic Pseudodiverticulum of Urethra. G. Eckhardt.—p. 421.

Treatment of Tuberculosis of Epididymis.—Out of 235 cases treated, Felsenreich is able to report the final results in 147. These cases were treated by operation, irradiation and injection. First of all, it is apparent that recurrences depend more on the presence and severity of a pulmonary tuberculosis rather than tuberculosis of the urogenital system. The same is true of the final results. Furthermore, all three methods of treatment yield equally good results; therefore, operation, at least semicastration, is not justified since conservative treatment yields as good results and does not expose the patient to the dangers entailed by operation. Ten of the sixteen deaths in this series occurred in cases in which only the lungs were involved; in six cases, pulmonary and urogenital tuberculosis was present. In not one case of pure urogenital tuberculosis did death occur. Good general treatment, with conservative preoperative and conservative operative treatment, is the best course of procedure. Radical operation should be reserved for patients of advanced years.

Actinomycosis of Kidney.—Recht reports a case in which the necropsy revealed suppurative nephritis in both kidneys, evidently secondary to an empyema of the sphenoid cells, and foci of actinomycosis in which gram-negative actinomyces were found. No other focus of actinomycosis was found elsewhere in the body. Therefore he concludes that this was a case of primary, isolated actinomycosis of the kidney.

Sarcoma of Seminal Vesicles with Multiple Metastases.—Junghanns relates the case of a man, aged 48, who came to operation with a diagnosis of tumor of the brain. Six hours after a subtemporal decompression, he died. The necropsy cleared the diagnosis. The brain was the seat of many sarcomatous metastases; one was found in the cardiac auricle. The primary tumor was situated in the left seminal vesicle. Microscopic examination disclosed that it was a giant cell alveolar sarcoma, the second now on record. All the symptoms in this case pointed to the brain; none to the pelvis. Junghanns also reports two cases of carcinoma of the seminal vesicle discovered at necropsy. Of 18,951 sections done in the years between 1893 and 1927, carcinoma was found in 2,012. Two of these were the cases of carcinoma of the seminal vesicle. In both cases the left gland was involved. One patient was aged 75; the other, 64. This brings the total of recorded cases of sarcoma to two and of carcinoma to twelve.

Threshold Value of Blood Sugar in Nephroses.—Fell tested the threshold value of the blood sugar in seven patients with various forms of nephrosis. After the sugar content of the blood had been determined, the patients were given an intravenous injection of a 30 per cent solution of dextrose. After that the sugar content of the urine and of the blood was ascertained. Tabular reports indicate that in patients with nephrosis the threshold value of the blood sugar is considerably higher than in normal persons. The author plans further investigations to determine the underlying causes (whether humoral, incretory or nervous) of the changes in the threshold value of the blood sugar of patients with nephrosis. He states that there are no indications for disorders in the intermediate carbohydrate metabolism. At least, a retardation in the depression of the blood sugar content was not observed.

Tophaceous Gout.—Lewy reports the case of a woman, aged 53. She asked medical aid on account of severe gastric disturbances. The examination revealed numerous peculiar growths on the arms and on the hands. The growths had developed during the last five years and were hard but not painful. The patient related that occasionally nodules opened and discharged a whitish mass. The subsequent ulceration that developed always healed quickly. The author thought of true gout and this diagnosis became more probable when an examination of the blood during a purine-free diet revealed a high uric acid content. However, when the contents of a nodule were examined the expected uric acid needles could not be detected and only an amorphous mass containing calcium carbonate and calcium phosphate was found. The case was now diagnosed as tophaceous gout. Roentgen examination revealed the chalky deposits as shadows. This was an additional proof for tophaceous gout because the urate deposits in ordinary gout are not visible in the roentgenogram. Roentgen diagnosis is therefore a valuable aid in differentiating between ordinary gout and the tophaceous form. The fact that the patient had an inoperable cancer of the stomach made frequent tests of the mineral metabolism difficult. However, it was found that the calcium content of the blood was considerably increased. Following the review of several cases of tophaceous gout from the literature the author assumes that tophaceous gout is perhaps not primarily a disorder of the mineral metabolism but is rather a chronic disease of the skin. The patient died as the result of the cancer of the stomach. Excision of the chalky nodules revealed that they were only in the subcutaneous connective tissue and that the underlying musculature was free from them. The author also describes the results of the microscopic examinations.

Relation Between Splenomegaly and Thrombosis of Splenic Vein.—A review of the literature and observations in two cases convinced Epstein that the diagnosis of thrombosis of the splenic vein is extremely difficult. To differentiate this condition from cirrhosis of liver and from Banti's disease usually requires a laparotomy, or it is correctly diagnosed only during the necropsy. However, a thrombosis of the splenic vein should be thought of in all cases of severe splenomegaly with hematemesis, digestive disorders, slight ascites, anemia and leukopenia. Thrombosis of the splenic vein is probable whenever the anamnesis or the clinical aspects do not give indications for cirrhosis of the liver. The thrombosis of the splenic vein is the secondary condition.

Relapse of Measles.—Liebig points out that an attack of measles generally results in immunity against further attacks. However, that there are exceptions to this rule has long been recognized. Some authors differentiate between a second attack of measles that is caused by a new infection and a relapse. The case observed by the author is significant for the problem of relapse of measles respectively for a second infection with measles, because the child was under clinical observation during the course of both attacks and a new infection during convalescence through another patient was not possible. The second exanthem appeared thirty days after the first one. The possibility that the child had German measles rather than measles was disproved by careful observations and the author is convinced that the child had a relapse of measles. Concerning the causes of such a relapse, nothing definite is known as yet. However, the author assumes that some patients have lost the capacity to develop antibodies against the virus of measles or possess it only temporarily. The cause of this abnormality in the immunity processes is not known, but, if the fever is an indicator of the resistance power of the organism against an infection, the absence of fever in the child and the long duration of the first exanthem indicate that it was not capable of forming antibodies.

Superiority of Broadly Built Persons Over Slender Types.—Schlesinger reports the results of investigations on the constitutional types of more than 2,000 children and young persons aged between 9 and 18 years. He discusses the method that was employed for the classification, the results of dynamometry and of spirometry, the developmental conditions, the anthropometric values and the constitutional anomalies. In the last part of the article he gives a tabular report, and on the basis of his investigations he comes to the conclusion that among the slender types the predisposition to constitutional anomalies, such as neuropathic conditions, sequelae of exudative diathesis, and muscular weakness that becomes manifest in postural abnormalities is much more frequent than among the broadly built children. However, what is still more important, the latter also show a physical superiority. The dynamometer registered their greater muscular power and tests with the spirometer indicated their greater vital capacity. It could also be demonstrated that in the broadly built types the circumference of the chest and the weight were greater in proportion to the body height than in the slender types, and underdevelopment and undernourishment were less frequent among the broadly built than among the slender. The author points out that from these observations on children and young persons it cannot be inferred with certainty that among adults the conditions are the same. But in spite of this, the investigations have proved that, for children and young persons, the broadly built type is the more desirable.

Prophylaxis of Thrombosis and Embolism During Puerperium.—Wachtel reviews various theories regarding the etiology of thrombosis and embolism, as well as the diagnosis and treatment of these conditions. In discussing the prophylaxis he stresses a nourishing and sensible diet and the regulation of defecation and of urination. During operations strictest asepsis, correct posture and the arrest of hemorrhage are essential. In cases of varicose veins, rubber stockings or bandages should be worn and prolonged standing should be avoided. Obliteration treatment of varicose veins is advisable even during pregnancy. The author recommends injections of a 10 or 15 per cent solution of dextrose. The treatment of varicose veins of the vulva is especially advisable during pregnancy. Women in whom thromboses have developed during former pregnancies should receive daily 3 drops of tincture of strophanthus, beginning several weeks before the confinement. *After delivery, medication with digitalis is advisable.* Some authors recommend blood transfusions. The author saw good results from dextrose infusions, particularly in anemic women after obstetric or gynecologic operations. As the most important factor in the prophylaxis of thrombosis and embolism during the puerperium, the author considers Walthard's method of gymnastics. The exercises should begin on the first day after parturition. The author describes the breathing and physical exercises for each day. Contraindications to the gymnastics are an existing thrombophlebitis, febrile conditions, great loss of blood, anemia and a serious operation. However, forceps operations and cesarean section are not contraindications. But if it is not possible to begin the exercises on the first day they should not be instituted later. In one instance of a cesarean operation the exercises were begun on the sixth day and the patient developed a pulmonary embolism and died. However, with the exception of this fatality, the results of the exercises were favorable. Among 100 puerperas, in whom the gymnastics had been omitted, there developed six cases of thrombophlebitis, whereas among several hundred others who had taken the exercises there was not a single case of thrombosis.

Cure of Myeloblastic Leukemia.—Gloor describes the clinical history of a patient with myeloblastic leukemia who came under his observation in 1927. Several examinations in the last two and one-half years prove that this cure is a permanent one. The case is of especial interest because the prognosis in cases of myeloblastic leukemia is generally unfavorable. In some instances temporary improvements are noted, but permanent cures are extremely rare and most cases have a fatal outcome after several months. The diagnosis myeloblastic leukemia was correct in this case. The therapeutic success cannot be ascribed to the one or to the other form of treatment but rather to the combination of the different treatments. The patient was given intensive arsenic treatment, received several roentgen irradiations, and intravenous treatment with mesothorium. These therapeutic measures effected a temporary reduction in the leukocytes but after that they increased again. Then a blood transfusion was made and this in turn was followed by roentgen treatment and then by another blood transfusion. After that normal blood formation set in. The same therapeutic procedures were later employed in other cases of myeloblastic leukemia but the improvement was either temporary or entirely absent.

Demonstration and Treatment of Diseases of Peripheral Arteries.—Roentgen examination of the arterial system of the extremities was performed by Sgalitzer et al. in twenty cases. An iodine preparation was used as contrast medium. The authors come to the conclusion that the method has diagnostic significance since it reveals obstructions or stenoses that are caused by arteriosclerosis, endarteritis or spasms, and it localizes an embolus or thrombus. In several instances, namely, in intermittent claudication and in beginning gangrene of the toes, temporary therapeutic effects were noted.

Experimental Prolongation of Pregnancy by Means of Corpus Luteum Extracts.—Miklòs states that the function of the corpus luteum and especially its hormonal secretion have been investigated by various authors. He reviews the results of these investigations and then describes his own experiments on rats. It was found that following several injections of corpus luteum extracts the pregnancy of the rats was prolonged not only beyond the average length but even beyond the longest term. Regarding the development of the young, the author states that some of them were somewhat heavier than young rats that had developed without the influence of corpus luteum extracts. It is also noteworthy that, in some of the animals in which the pregnancy was prolonged as the result of corpus luteum injection, the young were dead at birth. It is known that overterm pregnancies in human beings also frequently result in stillbirth. The author thinks that his experiments demonstrate that the corpus luteum influences the termination of pregnancy. However, he does not consider it the only factor. It was also noted that injection of corpus luteum extract on the last day of pregnancy did not cause a prolongation.

*So-Called Intestinal Infantilism. M. Edgren.—p. 440.
*Fibril-Forming Power of Epithelioid Cells in Tuberculous Tissue. I. Wallgren.—p. 450.

Conservative Treatment of Dacryocystitis and Dacryostenosis.—Kuhlefelt has treated conservatively even the gravest cases of dacryocystitis and dacryostenosis and on the basis of his experiences believes that operative intervention is rarely necessary.

So-Called Intestinal Infantilism.—Edgren reports thirteen cases treated from 1923 to 1929. Five patients died, three are well, and the fate of the remaining three is unknown. Investigations in two cases showed greatly lowered fat resorption, the loss of fat amounting to from 34.1 to 53.1 per cent of the fat intake.

Fibril-Forming Power of Epithelioid Cells in Tuberculous Tissue.—Wallgren's results support the view that the fibrils in tuberculous tissue develop from the epithelioid cells.

*New Method of Roentgen Examination of Symphysis Pubis in Women. T. Dale.—p. 782.
Course of Bile and Pancreatic Ducts in Patients with Necrosis of Pancreas. E. Hegge.—p. 786.

Syphilis-Arsphenamine-Paratherapeutic Jaundice: Attempt at Orientation.—Gjessing reports nine cases in syphilitic persons. He believes that the majority of cases of jaundice appearing during arsphenamine treatment, probably also most cases of posttherapeutic jaundice are of infectious nature. Although intertherapeutic or posttherapeutic jaundice can often be cured during arsphenamine treatment or by continued arsphenamine treatment, respectively, arsphenamine should, he says, as a rule not be used, as it is at present impossible to distinguish between the forms in which the treatment is advisable and in which it is dangerous. Even when the probable diagnosis is syphilitic jaundice, arsphenamine should generally be discontinued until the jaundice is past.

Grave Anemia: Two Cases.—Of Høst's cases, both fatal, the first was diagnosed as aplastic anemia, the second, regarded as a peculiar, nonpernicious anemia or an aleukemic myelosis. Massive and frequent blood transfusions resulted in but slight rise in the erythrocyte count.

Phlegmonous Duodenitis: Case.—In Hjort's patient with high fever and all the indications of gravest peritonitis, no signs of peritonitis were found on operation or at necropsy, but in the duodenal wall there was a phlegmon, together with a large number of apparently acute ulcerations in the mucous membrane.

Demonstration of Tubercle Bacilli by Cultivation.—Sundt thinks that in the examination of sputums this method will never supplant direct demonstration of tubercle bacilli, but after repeated negative examinations cultivation may well be attempted. Hohn's method was used by him in twenty-eight such cases, with cultures of bacilli in seven. In his opinion cultivation from pleural exudates and pus offers great possibilities. In examination of the urine the method seemed somewhat less reliable than inoculation in guinea-pigs, but he agrees with other investigators that the two procedures should be used simultaneously.

New Method of Roentgen Examination of Symphysis Pubis in Women.—Dale passed a tube of aluminum 1 mm. thick into the vagina directly back of the symphysis, the film being placed on a holder in the tube. The results of examination in seventy-nine cases are presented. The roentgenograms gave a clearly defined picture with correct measurement of the distance between the pubic bones.

Treatment of Hepatic Complications Accompanying Calculus in Ductus Choledochus.—Abrahamsen definitely recommends energetic attempts with dextrose-insulin treatment in case of stone in the ductus choledochus with cholangeitis and parenchymatous degeneration of the liver. His experiences in the two cases reported wholly agree with the favorable results obtained in medical cases by dextrose-insulin treatment of acute or subacute atrophy of the liver. He emphasizes that his patients, both greatly exhausted were operated on in lumbar anesthesia, without the further weakening of the liver due to chloroform and ether.

*Etiology of Polyarthritides. V. Starcke.—p. 669.
Effect of Operative Interventions on Blood Platelet Count. J. Foged.—p. 678.
Viper Bite. V. Poulsen.—p. 681.

Etiology of Polyarthritides.—In Starcke's review, rheumatic polyarthritides are classed as an interference phenomenon due to various causes that may vary in significance and intensity from type to type and from case to case. Infection is particularly emphasized among the etiologic factors in polyarthritides, and streptococci play the most important part. Pathologic conditions of the joints due to streptococci will probably be regarded as a nosologic entity, like tuberculosis of the joints. The susceptibility to infection and the different characteristics in polyarthritides must depend largely on constitutional differences. Greater importance must be attached to endocrine disturbances as factors in the etiology and pathogenesis. The bibliography contains 149 references.

GALLSTONES IN THE AMPULLA OF VATER *

E. STARR JUDD, M.D.
AND
JAMES M. MARSHALL, M.D.
Fellow in Surgery, the Mayo Foundation
ROCHESTER, MINN.

The bile in passing from the liver to the intestine passes through a duct of more or less uniform diameter, which is suddenly narrowed at the point where it enters the duodenum at the papilla of Vater. Anatomically a stone would be most likely to meet resistance at this point in its passage down the common bile duct. Likewise at this point the flow of bile would be most easily obstructed. The average diameter of the opening at the tip of the papilla is about 3.5 mm. Just proximal to this opening is found the dilated pouch, approximately 1 cm. in diameter, into which the common bile duct and pancreatic duct usually empty. This is the so-called diverticulum or ampulla of Vater. Fenger, many years ago, described the symptoms of stone lodged in the ampulla, the "ball-valve stone of Fenger." Because a stone at this point causes a somewhat characteristic chain of symptoms, we decided to review a series of such cases seen at the Mayo Clinic.

A group of 160 cases was selected in which one or more stones were found in the ampulla at operation and in which other stones were not found in the hepatic or common bile ducts. In many other cases stones were found lodged in the ampulla, but they were associated with stones in other portions of the extrahepatic bile ducts; such cases were not included.

As would be expected, the majority of the patients were past middle age, the average age being 50 years; three fourths of the patients were aged between 40 and 60 years. The youngest patient was a boy, aged 15 years, who had a history of repeated attacks of typical biliary colic associated with chills and fever over a period of eighteen months, although he had never been jaundiced, according to his parents' observations. A diseased* gallbladder containing multiple stones was removed. The common bile duct was found to be dilated, and a stone 5 mm. in diameter was removed from the ampulla.

The ratio of females to males was approximately 2: 1, which is about the usual ratio of frequency of stones in the gallbladder, in the two sexes.

In 72 (45 per cent) of the 160 cases, one or more operations had been performed on the biliary system; in several cases as many as three or four operations had been performed: cholecystostomy, cholecystectomy or choledochostomy, or all three. In 55 per cent of the cases, relief had not been obtained and the patients continued to suffer from the symptoms that they had had prior to the operation. In 24 per cent of the cases there had been a period of complete relief following the operation, varying from three months to thirty years; in the remaining 21 per cent some relief had been obtained, but enough of their original symptoms persisted to induce the patients to seek further relief. Fifty-four patients had had cholecystostomy performed, thirty-three had had cholecystectomy, and seven had had choledochostomy. Seventeen (10.6 per cent) of the patients had external biliary fistula when they presented themselves for examination at the clinic, some of them for as long as two years.

SYMPTOMS AND DIAGNOSIS

In the diagnosis of stone in the common bile duct a thorough and complete clinical history usually offers the most useful clue to the diagnosis in spite of recent diagnostic refinements and laboratory aids. The most characteristic feature of stone in the common bile duct is the intermittent nature of the symptoms. Osler described the classic symptoms of stone in the common bile duct as paroxysms of colicky pain, chills and fever, and jaundice, followed by intervals of comparative or complete freedom from symptoms. Most patients suffering from stone in the ampulla of Vater present a history of intermittent trouble, although any one or more of these symptoms may be lacking. It is well known that a stone in the common bile duct may lie dormant for months or years without producing appreciable symptoms. The stone may then lodge against the wall of the duct or at the papilla, producing irritation of the mucous lining of the duct with inflammatory reaction and edema, occluding the duct around the stone and giving rise to biliary obstruction. This is the probable explanation of many of the attacks of colic. If there is infection, as there usually is in the bile behind the obstruction, symptoms of sepsis appear, and if the obstruction is more or less complete, jaundice becomes evident. We recently operated on a woman, aged 76, who presented all the classic signs and symptoms of stone in the common bile duct. The history in this case was that of only six months of repeated attacks of severe right upper abdominal colicky pain extending through to the back, associated with chills and fever up to 104 F. and followed by residual soreness and jaundice lasting from a few days to a week or two. During the eight weeks prior to admission the attacks had been frequent, each time with severe pain, chills and fever, and followed by jaundice; the succeeding attack would come before the jaundice had entirely cleared. The patient was jaundiced; the serum bilirubin was 8.5 mg., and the van den Bergh reaction was direct.

---

* From the Mayo Clinic.

* Read before the Section on Surgery, General and Abdominal, at the Eighty-First Annual Session of the American Medical Association, Detroit, June 26, 1930.

During the period of observation in the hospital the jaundice subsided somewhat, and the flow of bile from the duodenum was moderately free. At operation the common bile duct was found to be about 2 cm. in diameter. A solitary stone 15 mm. in diameter was lodged in the ampulla. The gallbladder was almost completely destroyed.

Pain is the most common symptom of stone in the common bile duct. The pain usually is of the classic colicky type. *In our cases the pain was either mild or* severe in 155 of the 160 cases. In five cases a most careful examination could not elicit a history of pain of any kind. Many of the patients, especially after a long history of recurring attacks of colic, followed by a period of relative comfort, gave a history of several months of more or less constant dull pain in the upper part of the abdomen in addition to the attacks of colic. Jordan recently studied 106 cases of stone in the common bile duct at the Mayo Clinic. In six of these cases there was no history of pain at any time, and there were ten additional cases in which the onset of jaundice was painless. The attacks of colic were usually associated with a gastric disturbance: epigastric fulness, bloating, nausea and vomiting.

Intermittent jaundice was present in 117 (73 per cent) of our cases. It usually lasted a few days or a few weeks and was followed by a period of complete freedom. There were thirty-seven cases (23 per cent) in which a history of jaundice could not be elicited at any time during the course of the illness. Constant and apparently complete jaundice was noted in only six of the cases for a period of more than a month. There were seven patients who had been constantly jaundiced for one month or less at the time of admission and it was apparent that they had reported for examination during their first attack of jaundice. The serum bilirubin, as estimated by the van den Bergh test, gives a direct reaction and usually varies if the patient is kept under observation for a period of time. In our series the highest reading for serum bilirubin was 22.7 mg. in a case of apparent complete obstructive jaundice of five months' duration.

Symptoms of sepsis, as evidenced by attacks of chills and fever, were present in eighty-one (51 per cent) of the cases. In many of the cases the ague-like paroxysm was severe, amounting to rigor, with the temperature going to a peak of from 104 to 105 F., followed by a rapid decline.

Duodenal drainage, accomplished by the passage of a small soft Rehfuss tube in the duodenum, affords a valuable clue as to whether or not bile is passing from the duct into the duodenum. Bile was recovered on duodenal drainage in 83 per cent of the cases. In several of the remaining cases only one attempt at duodenal drainage was made and it is possible that further attempts at drainage might have recovered bile in a higher percentage of cases. Certainly in most cases of stone in the common bile duct, bile in varying amounts can be recovered from the duodenum if duodenal drainage is done repeatedly.

There was a definite group of cases of stone in the common bile duct in which the only characteristic symptom was severe colicky pain. An example of such a case is a woman who was recently operated on at the clinic. She was aged 57, and gave a history of typical biliary colic dating back twelve years. In the four years before admission, the attacks had been frequent; cholecystectomy had been performed elsewhere eighteen months before admission. There had been no jaundice prior to operation. Three weeks after operation she had a recurrence of colics, and they were more frequent and more severe, each requiring a hypodermic for relief. There never was a history of chills, fever or jaundice. At operation the common bile duct was found to be enlarged several times its normal size. It was thin walled and blue, and contained normal bile under tension. An irregularly shaped stone about 7 mm. in diameter was found lodged in the ampulla. No other stones could be found in the duct, and the probe passed freely into the duodenum.

OBSERVATIONS AT OPERATION

In 124 (77 per cent) of the 160 cases a single stone was found in the ampulla at operation. In fifteen (9.5 per cent) there were two stones and in twenty-one (13 per cent) there were more than two. The stones varied in diameter from 3 mm. to 2.5 cm. In 110 cases (69 per cent) there were stones in the gallbladder as well as in the ampulla; the stones in the gallbladder were found at the clinic, or a definite history was elicited of stones removed from the gallbladder at operation elsewhere. There were forty-two (26 per cent) cases in which a stone in the ampulla was the only stone present in the biliary system and there were eight cases in which a stone in the ampulla was the only stone found at the time of operation at the clinic, but we could not be sure that stones had not been removed previously elsewhere. *In many of the cases the stone in the ampulla was found* firmly lodged and adherent to the mucosa of the duct. In others the stone was small and round and apparently floating free.

As has been noted, the condition of the gallbladder at operation was frequently somewhat fibrous and contracted, often down to a small amount of fibrous tissue appearing as a small pouch protruding from the common bile duct. There were twelve cases in which there was a cholecysto-enteric fistula. In nine cases the fistula opened into the duodenum, in two cases into the colon, and in one case into the stomach.

In operating to remove stone in the ampulla, we make a longitudinal incision in the common bile duct near the point of entrance of the cystic duct and then explore the duct with a scoop, forceps or examining finger. This procedure was carried out in all but four of the cases in our series; in these, transduodenal choledochostomy was performed because the stone could *not be removed by the other method.*

It is not always easy to make a diagnosis of stone in the ampulla without opening the common bile duct. Because of the situation of the stone between the duodenum and the pancreas, it is difficult to palpate it even if it is of considerable size. Undoubtedly some of the stones would have been missed in our cases had not the common bile duct been opened on the strength of a history suggestive of trouble in the duct. Whether or not a stone can be palpated in the ampulla or common bile duct, it is advisable to open the duct and explore it, if there is a history of recurring chills, fever and jaundice, and if the common bile duct is found to be dilated at the operation. Although noncalculous intermittent biliary obstruction and strictures in the common bile duct may be the cause of persistent symptoms noted after cholecystectomy, many of the failures to relieve symptoms can be attributed to failure to remove a stone lodged in the ampulla.

During the years 1928 and 1929 we operated on 1,663 patients who had gallstones. In ninety-two (5.53 per cent) the gallstones were found only in the common duct. One hundred and twenty-seven (7.6 per cent) had stones in both the gallbladder and the common duct. In the remaining 1,444 patients (86.83 per cent) the stones were found only in the gallbladder. Thus it will be seen that of the 1,663 patients, all of whom had gallstones, 219 (13.2 per cent) had stones in the common duct.

TECHNIC OF OPERATION

The first technical point to be considered in the operation is an incision sufficiently large to admit of the best possible exposure. Exposure of the operative field is more important in these operations than in almost any other. After the incision has been made and the packing off has been completed, the common bile duct should be freed as completely as possible so that the different technical steps may be carried out without danger of injury to other important structures.

When the duct has been exposed it is usually best to grasp it with two delicate Allison forceps. In certain cases it will be better to use the stone in the duct as a guide to the duct, holding the stone with the fingers of one hand, and making the incision through the duct down onto it. The opening in the duct should be large enough to admit the examining finger if the duct is dilated. A fairly large longitudinal incision in the duct can be readily repaired without a tendency to the formation of stricture. Not infrequently, a scoop or a probe will pass by a stone, giving the impression that there is no stone. However, when the duct is large enough to admit a finger, the likelihood of overlooking a stone is reduced considerably.

After the incision has been made in the duct, the bile, débris and loose stones should be gently sponged out and then all of the other free stones should be removed from the common and hepatic ducts as gently as possible. We are certain that considerable harm can come from too vigorous irrigation of the bile ducts, although several times we have been able to flush stones out of the ducts of the liver that probably could not have been removed in any other way.

Removal of the stone or stones from the ampulla is best accomplished by first passing a scoop into the ampulla, then guiding the scoop with the fingers outside the duodenum, gradually manipulating the stone until it is crowded into the hollow of the scoop and holding it in this position as the scoop is gradually withdrawn. We find that the surest way to palpate a small stone in the ampulla, especially when the surrounding pancreatic tissue is swollen, is to pass as large a probe as will comfortably fit into the common bile duct gently down into the ampulla, and then to palpate the ampulla, leaving this instrument in place as a guide. In many cases the duct is greatly elongated, and there may also be considerable enlargement of the head of the pancreas, which makes it difficult to locate the ampulla even when there is a fair-sized stone in it. One of the best instruments for locating the ampulla and also for demonstrating whether it is open or not is a large curved hemostat. We have frequently been able to pass such an instrument into the duodenum when nothing else would go through the ampulla.

We realize how difficult it is to be sure that all stones have been removed. Occasionally they will be overlooked when the greatest care has been exercised, and in some instances they will reform. We do not feel that efforts to clear out all calculi should be carried to the point of too great trauma to the tissues. We have seen one case of stricture following removal of stone from the ampulla. Apparently this rarely occurs, but severe infection may follow energetic probing and dilating. If the gallbladder has been removed or destroyed, the activity of the sphincter at the ampulla will be overcome so that there will be free passage for small stones or débris into the duodenum. We believe that it is far more important to provide prolonged drainage by T-tube in these cases of stone in the ampulla than it is to dilate the passage into the duodenum forcibly. Drainage of the duct should always be carried out after removal of stones from the ampulla, and this is best done with the Deaver T-tube. By this method, complete control is obtained of the flow of bile after the wound has healed around the tube. If the lower end of the duct is opened widely, then bile will pass through the tube into the duodenum, whereas if the ampulla is closed from swelling or any other cause, the bile escapes to the outside through the long arm of the tube. Often when bile is needed for the welfare of the patient it may be forced into the duodenum by clamping the outside tube. Another advantage of this plan of drainage is that this tube may be used as MacArthur suggests, for the administration of fluids, dextrose and any form of liquid nourishment.

In our group of 160 cases of removal of stones from the ampulla, there were eleven deaths, a mortality of 6.8 per cent. In four cases in the series a transduodenal operation was performed; this method was used because it did not seem possible to remove the stone through an incision in the common bile duct. In all of the four cases the common bile duct was first opened and an attempt was made to remove the stone through that incision. Failing to get it in this way, the duodenum was opened and the stone was removed through the duodenum. We now believe that it is always possible to remove stones from the ampulla through an incision in the common bile duct, and that operations through the duodenum are seldom necessary and are carried out at a considerably higher risk. We have not, however, attempted to perform the operation just as McBurney described it.

ILLUSTRATIVE CASES

CASE 1.—A man, aged 58, came to the clinic, May 30, 1929, complaining of recurring attacks of severe pain in the upper part of the abdomen. Twenty-two years previously, he had had a severe attack of colic, followed by jaundice. The colic recurred at infrequent intervals until operation was performed elsewhere in April, 1928. Cholecystostomy was done and stones were removed from the gallbladder. The wound drained for three and a half weeks, and then closed. The patient was then well until six weeks before admission, when he had had a severe typical attack of gallstone colic, and one week later he noticed dark urine and clay-colored stools. During the three weeks prior to admission he had had three attacks of upper abdominal pain with chills and fever, the last one, with jaundice, ten days before admission. Otherwise, he had a rather typical history of peptic ulcer dating back eight or ten years, with pain coming on from two to three hours after meals, relieved by taking food or alkaline powder.

The patient was somewhat emaciated, and weighed 23 pounds (10 Kg.) less than his usual weight. He was faintly jaundiced; the serum bilirubin was 4.3 mg. for each 100 cc., and the van den Bergh reaction was direct. Tenderness was elicited in the right upper part of the abdomen. The blood urea was 34 mg. for each 100 cc. Roentgenograms of the stomach and duodenum showed duodenal ulcer. All other laboratory examinations were negative.

At operation, June 6, the gallbladder was found to be somewhat distended but did not contain stones. The common bile duct was opened and was explored with a scoop, but stones were not found. The scoop passed readily through the ampulla into the duodenum. There was a large subacute duodenal ulcer on the anterior surface of the duodenum. The patient's general condition was not good, so a rubber catheter was stitched into the jejenum after the method of Witzel instead of gastro-enterostomy. The catheter was brought out through a stab wound in the left rectus abdominis muscle. A Mayo-Robson hepaticus drain was left in the common bile duct and a dressed tube was left in the gallbladder.

During the first three days after operation, there was drainage of rancid, sour-smelling, thin, flocculent bile-covered fluid, 1,175, 1,530 and 1,425 cc., respectively. Methylene blue (methylthionine chloride-U. S. P.) given by mouth appeared copiously in the drainage material. Examination of the material showed the presence of a large amount of starch-splitting enzyme. On the third day the blood urea was 67 mg. and on the fourth day 74 mg. for each 100 cc., and the patient appeared extremely ill. The margins of the wound were reddened and irritated from contact with the drainage material. On the fourth day the end of the Mayo-Robson drain was connected directly with the jejunostomy tube so that the fluid draining from the common bile duct poured directly back into the jejunum. The patient was given fluids in abundance, including physiologic solution of sodium chloride intravenously, 2,000 cc. daily. He seemed to improve but on the seventh day bronchopneumonia developed and he died on the eleventh day.

At necropsy the Mayo-Robson tube was found in place in the common bile duct. There was slight necrosis of tissue around the tube as it coursed over the duodenum. The common bile duct was 12 mm. in diameter and there was a stone, 6 by 8 mm., impacted in the ampulla. The pancreatic duct entered the common bile duct 1 cm. above the sphincter of Oddi and therefore proximal to the impacted stone. Other stones were not found in the ducts or gallbladder. A large subacute ulcer on the anterior surface of the duodenum and two smaller ulcers on the posterior wall were found. The lungs showed extensive bilateral bronchopneumonia.

Case 2.—A woman, aged 68, admitted to the clinic, March 30, 1930, gave a history of recurring attacks of upper abdominal colic dating back twenty years, each attack with a sudden onset and requiring hypodermics for relief. There had never been any chills, fever or jaundice prior to cholecystostomy, which had been done elsewhere five years before admission. At the time of operation the gallbladder was drained and many stones were removed. After the operation she had a rather slow convalescence. The sinus remained open intermittently for several months, but then it closed and the patient was well for one year. Then she had a recurrence of the colicky attacks similar to those she had had before the operation, but in each case they were followed by a period of mild jaundice for from two to ten days.

On examination the patient was found to be rather obese and to have moderate benign hypertension. The blood pressure was 220 systolic and 120 diastolic. There was slight tenderness in the epigastrium. Duodenal drainage showed ample bile on two occasions. The serum bilirubin was 4.1 mg. for each 100 cc., and the van den Bergh reaction was direct. A flat roentgenogram of the area of the gallbladder was negative. There were slight changes in the electrocardiographic tracing, but there were no signs of cardiac decompensation. The coagulation time was eight minutes.

At operation the gallbladder was contracted and completely destroyed. The common bile duct was dilated and a single stone 1 cm. in diameter was lodged in the ampulla. There was a moderate amount of cholangeitis. The gallbladder was easily removed, a stone was removed from the ampulla and a T-tube was sutured into the opening of the common bile duct.

Following the operation the T-tube drained freely, but on the fourth postoperative day there were signs of cardiorenal insufficiency and the blood urea was 124 mg. for each 100 cc. Fluids were injected intravenously, and the blood urea promptly returned to normal. By the twelfth day the jaundice had cleared and clamping of the tube was begun. On the twenty-eighth day the T-tube was removed without difficulty. At that time the general condition of the patient was good; she was free from jaundice and there was ample bile in the stools. Following the removal of the T-tube the sinus healed in twenty-four hours, and recovery was complete.

Case 3.—A woman, aged 44, admitted to the clinic, March 9, 1930, gave a history of having had rather typical attacks of gallbladder colics frequently during the preceding year, several of which were followed by dark urine and light stools; after one attack three months before admission, definite jaundice was present. Nine weeks prior to admission she was operated on elsewhere and the gallbladder was removed and was reported to be infected, but without stones. After the operation she did not have colic, but the stools continued to be light-colored and there was a persistent biliary sinus through the operative wound. One week before admission this sinus stopped draining and the patient had since had pain across the upper part of the abdomen, nausea and vomiting, and jaundice.

On examination it was found that the patient was moderately jaundiced. The serum bilirubin was 4.9 mg. for each 100 cc., and the van den Bergh reaction was direct. The coagulation time was eight minutes. There was moderate anemia; the hemoglobin was 65 per cent and the erythrocytes numbered 3,520,000. There was a small sinus in the operative incision in the right upper quadrant of the abdomen which, at the time of examination, was not draining. The temperature was normal.

On duodenal drainage on several occasions following admission, a fair amount of normal-appearing bile was recovered from the duodenum. During the six days' observation in the hospital before the operation, the patient felt better and the jaundice subsided somewhat.

At operation the sinus tract led down to a good-sized remnant of the lower end of the gallbladder. The common bile duct was dilated and a stone 1 cm. in diameter was removed from the ampulla. It was thought that a probe passed through the ampulla into the duodenum, and normal-appearing bile came from the common bile duct. There was mild hepatitis and mild biliary cirrhosis. A T-tube was sutured into the common bile duct, and the remnant of the gallbladder was removed.

The postoperative convalescence was entirely uneventful. The T-tube drained freely from 500 to 700 cc. of normal-appearing bile each twenty-four hours. Clamping of the tube was begun on the fourteenth day and was continued progressively until the tube was removed on the twenty-eighth day. At that time the patient was entirely free from jaundice, the stools were of good color and her general condition was good. The sinus, following the removal of the T-tube, healed within forty-eight hours, and recovery was complete.

RELATION OF THE SPLEEN TO JAUNDICE *

ROBERT LEE PAYNE, M.D.
NORFOLK, VA.

In a consideration of the relation of the spleen to jaundice it must first be borne in mind that the erythrocyte is the chief source of hemoglobin from which the formation of bile pigments must originate. Therefore, the relation of the normal and the pathologic spleen to red blood cell destruction is the hub around which the entire discussion must revolve.

The spleen may destroy red blood cells by an intracellular process which is dependent on the action of the macrophages or by an extracellular action which must be distinctly a lytic process.

The formation of bile pigments in the spleen must be dependent on a definite splenic hemolysis, but to argue a hemolytic function for the spleen based on the blood picture of splenectomized animals encounters difficulties that cannot be surmounted.

In the presence of jaundice associated with a large spleen one is at once confronted with the fact that there is both an intrahepatic and an extrahepatic formation of bile pigments. The extrahepatic source of bile pig-

ment is in the reticulo-endothelial system, of which the spleen probably plays a minor part, while the bone marrow is really the chief depot for bilirubin formation. In a careful review of the literature there is nothing to confirm a controlling influence of the spleen on the formation of bile pigments in the liver, and all researches make the the conclusions most doubtful.

Mann[1] has shown that the large proportion of bilirubin in the blood is formed in the bone marrow; hence, in the discussion of the spleen in its relation to jaundice, it at once becomes necessary to consider the relation of the spleen to the bone marrow. It is a rather generally accepted idea that the blood picture after splenectomy indicates that the bone marrow has partaken of a resulting stimulation. This conviction follows the increase in red blood cells, normoblasts and blood platelets, and especially convincing is the presence of Howell-Jolly bodies in the red blood cells. Equally interesting is the consideration of the reticulocyte count in the presence of hemolytic jaundice and obstructive jaundice. In familial hemolytic jaundice and in sickle cell anemia there is a high reticulocyte count at all times. In hemolytic jaundice (not familial) the reticulocyte count shows only a moderate increase, while in obstructive jaundice there is no increase of reticulocytes and no increased fragility of the red cells. However, it does not theoretically follow that a normal or pathologic spleen has any inhibitory action on the bone marrow. Lauda[2] says that the changes in the red blood cell count after splenectomy cannot be interpreted by the exclusion of the spleen and, further, that destruction of red blood cells in the spleen has not been proved for, so far, it has not been established that the efferent blood in the splenic vein contains fewer red blood cells than the afferent blood to the organ through the splenic artery.

Barcroft[3] ably reasons that irritation of the bone marrow after splenectomy is due to the reduction of the organism's total hemoglobin content and is comparable to the state of acute anemia from massive loss of blood which is generally conceded to produce bone marrow stimulation as evidenced by the blood picture. Barcroft holds that the spleen is merely a large depot of hemoglobin which empties by contraction and that the entire depot supply is summarily depleted by splenectomy. If Barcroft's conclusions are to be accepted then there is at once some basis of explanation for the source of abnormally large amounts of bile pigment in pathologic hypertrophy of the spleen and can thereby theoretically account for a definite relationship of the enlarged spleen and the presence of jaundice. With further reference to the relation of the spleen to the bone marrow one must consider the question of reduced resistance of the red blood cells in the presence of a pathologic spleen, for it is well established, beyond controversion, that the resistance of the red blood cells is invariably increased after splenectomy, whether the organ is normal or pathologic. Further, it is well known that this increased resistance of the red blood cells persists for many years after splenectomy. However, as an argument against the spleen alone and contending for the relation of the spleen to the bone marrow, it may be added that the difference in the resistance of the red blood cells in the splenic vein and the vascular supply of other regions has not been proved.

Following Barcroft's conclusions that the spleen is a depot for hemoglobin or a storehouse of iron deposit, one can again find some justification for the so-called clinical syndrome of splenic jaundice as follows: In both physiologic and pathologic conditions it is known certainly that the red blood cells are broken up in the peripheral circulation: The first step in this process is most probably due to aging of the cells and the resulting products are hemoglobin, stroma and iron pigment which the German workers designate as Schlacken. This slag is taken up by the spleen and in the presence of exaggerated function or hypertrophy there may be a failure of the cellular activity or the filter function of the organ and thereby pigments may escape into the general circulation and be deposited as jaundice. Lauda says that normally this would be a passive rôle of the spleen but in disease condition with hypertrophy the process would probably be an active one.

BILIRUBIN FORMATION IN THE SPLEEN

There are many researches which justify the conclusion that under physiologic as well as under certain pathologic conditions the spleen influences the production of bilirubin. There are may ways by which the spleen may influence the process of changing the red blood cells into bilirubin, yet knowledge in this respect is defective. It may, however, be concluded with certainty that the spleen has an active part in the destructive metamorphosis of blood but it must be conceded that the spleen in some measure produces bilirubin which is derived from the products of hemoglobin and stroma following decomposition or fragmentation of the red blood cell. This can hardly be called a hemolytic process since lysis is often completed in the peripheral circulation before the red blood cells reach the spleen, thus accounting for the destruction of hemoglobin in the spleen.

McLeod and Pearce[4] state that the blood of the splenic vein contains more bilirubin than arterial blood. These authors also state that the veins of the bones contain more bilirubin than arterial blood. To support this contention Haldeman,[5] by the berlin blue method of identifying iron-containing pigment, concludes that the greater percentage of bilirubin is formed in the bone marrow while the liver, spleen and lymph nodes play a lesser rôle in this production.

It has been repeatedly stated in literature that the jaundice of hemolytic icterus disease is not a true jaundice but is due to the deposits of hemosiderin in the tissues. Stanley Cooke has demonstrated that hemosiderin is identical with ferric hydrate and results from changes of iron deposited in the splenic sinuses. Iron is liberated by the breaking down of hemoglobin into bilirubin; and, since it is known that the iron content of the spleen is fairly constant, Barcroft's conclusions may be concurred in that the spleen is merely a storage depot for iron until this is again utilized in the building up or formation of new hemoglobin. Barcroft states that hemosiderin is found in the splenic sinuses as a brown or blackish material and is expelled into the general circulation each time the spleen contracts. He further states that he has never seen it in the splenic artery but that it constantly occurs in the splenic vein.

[5] Haldeman, K. O.: A Histologic Study of the Formation of Bile Pigment, Arch. Path. **7**: 993-1011 (June) 1929.

In the light of present knowledge I think that I am forced to conclude that the pigmentation of hemolytic icterus is due both to hemosiderin and to bilirubin, which, being excessive in the general circulation, is deposited into the tissues. Associated with the splenic enlargement of hemolytic icterus and pernicious anemia there is always associated hyperbilirubinemia which cannot be explained as entirely splenic in origin, for the failure of the liver to filter and deliver this excess of bilirubin must have a most important bearing on the condition of so-called splenic jaundice.

McNee's[6] classification of jaundice into three types lends a plausible explanation to this problem of splenic jaundice. In his third classification he states that the jaundice is due to an excessive load of the products of blood destruction which the polygonal cells of the liver are unable to handle and as a result of this faulty transmission the bile pigments are taken up by the hepatic veins and are thus carried into the general circulation. One may accept the condition of hemolytic icterus as an entity which would fairly represent the various pathologic conditions of the spleen in which so-called splenic jaundice is known to exist. However, one is forced to conclude from all of the studies of this problem that hemolytic jaundice is a disease of the entire hematopoietic system and the source of jaundice is not only from the spleen but also from the liver and bone marrow, and the good effects of splenectomy in this condition can probably be explained as follows:

The pathologic spleen delivers its blood (containing large amounts of pigment) directly and in large amounts to the liver, and the polygonal cells are unable to filter the excessive load put on them. After splenectomy this excessive load on the liver is lifted, yet destruction of the red blood cells continues to take place, not only in smaller quantities but in remote areas, such as the bone marrow and other remaining parts of the reticulo-endothelial system. However, these products of red blood cell destruction, coming from areas remote from the liver, reach this organ by a longer and slower route and probably in a much less concentrated form; hence the liver cells are better able to deliver the pigments into the bile ducts.

CONCLUSIONS

From a correlation of research facts taken from the literature up to the present date, I think that I am justified in concluding as follows:

1. A certain amount of red blood cell destruction takes place in the spleen.
2. A certain amount of bilirubin is formed in the spleen.
3. The amount of red blood cell destruction and bilirubin formation in the spleen is relatively small as compared with the consummation of these functions elsewhere in the body.
4. That hyperbilirubinemia associated with dysfunction of the spleen is dependent on not only the spleen but the entire hematopoietic system must be considered as an important contributing factor in evaluating the relation of the spleen to jaundice. Particularly must it be remembered that there is commonly associated a hepatitis in which failure of the liver cells to filter bile pigments represents an active rôle in the production of the jaundice.

THE CLINICAL SIGNIFICANCE OF JAUNDICE *

M. A. BLANKENHORN, M.D.
CLEVELAND

The clinical significance of jaundice has been the same for the past twenty years or more. Jaundice should have no different meaning in the eyes of the surgeon than it has for the physician. The first question occurring to any one contemplating the jaundiced patient regardless of all else should be, Is there stoppage of the bile ducts? When this query cannot be answered in the affirmative, jaundice becomes a medical problem and the physician proceeds to make hard work of its solution. As long as the physician continues to classify his nonsurgical jaundiced patient by old fashioned and established methods, his job is not so difficult. He makes it easy by the use of convenient names such as catarrhal jaundice, infectious jaundice or icterus gravis as determined by certain more or less related symptoms.

Whenever the physician undertakes a rational study of the patient and attempts to speak of this disease in pathologic physiology, study lags for want of methods; and although words are present to speak in physiologic terms, ideas are very scanty. The physician makes his job harder still because of what he knows in an incomplete way about the association of jaundice with blood diseases. Charged with that responsibility of those half known facts he has set himself to a lot of testing of the blood and the bile, none of which work, unfortunately, helps the patient very much. From this welter, the physician has not yet been extricated. Although the physiologist and the pathologist have in recent times thrown great light on the problem of the formation of bile pigment and on certain functions of the liver, little has developed to help the surgeon with his question about stoppage of the ducts. After all, whether to physician or to surgeon, the first and most important *significance of jaundice is the possibility of stoppage* of the ducts. The principal topic of this paper, then, is obstructive jaundice.

To make a diagnosis of obstructive jaundice, one of the three common procedures is generally followed: 1. If there is a history of colic, one argues from cause to effect and says that the stone that causes colic obstructs the duct. 2. Tests for liver disease or tests of liver function can be done, and the finding of liver disease or disordered function excludes obstruction by substituting another cause. 3. The symptom of jaundice can be studied to see whether obstruction of the ducts alone could give such a distribution of bile pigment.

As to the first procedure, nothing more need be said, because the issues are simple. As to the second—the liver tests—much has been said because the issues are obscure, not because any of the tests are especially helpful. I do not refer here to cholecystograms by Graham's method. These tests, being for gallbladder function, are to be classed with the history of colic in simplicity and clearness. This method of study, which has become the most valued of all, unfortunately cannot be used when jaundice has fully developed.

All other dye tests apparently cannot be used when jaundice is present, or if they are used the dyes are disposed of by the liver in the same manner as is bile pigment. The new dye described by Evarts Graham may be an exception.

As to other tests, no examination of the blood serum can explain the mechanism of jaundice even so far as to say whether the ducts, the liver capillaries or the extrahepatic pigment formation is at fault.

The van den Bergh tests have designated and still are said by some to designate the part of the mechanism at fault. Since the van den Bergh test continues to be lugged along in the journey of medical progress as baggage of possible value, I will not dispose of the test with a single gesture.

This very promising test was originally claimed to detect in the blood bile pigment which had been formed outside the liver and which had not yet been passed through the liver filter. In this instance, the reaction was said to be indirect and indicated jaundice due to excess or anomalous extrahepatic pigment formation. The method might also indicate jaundice when extrahepatic pigment formation was normal, but the liver filter, being disordered, was incapable of removing this normal product so that an intrahepatic jaundice resulted—likewise the "van den Bergh indirect." Whenever, on the other hand, normal pigment from its usual source, wherever that might be, had successfully passed the liver filter but was collected into obstructed ducts and again taken up by the circulation to cause jaundice, "the van den Bergh direct" was the resulting reaction. This was necessarily classed as obstructive or intrahepatic jaundice—the sort under consideration here.

There can be no doubt that the van den Bergh test results in several reactions, sometimes direct and other times indirect, but there is now no good reason to believe that the direct reaction is caused solely by bile pigment that has passed the liver and then got back into the blood by some means as a result of obstruction, nor is there reason to say that the indirect reaction is caused by bile pigment of a peculiar sort that has not yet gone through the liver filter. Too many exceptions have made the theory of the two kinds of pigment not acceptable, and furthermore other good explanation is found for the two sorts of tests. Numerous writers have reported that the van den Bergh direct reaction is found when bile pigment appears in the urine, and the indirect reaction only when pigment remains in the blood and cannot get into the urine. Others, in harmony with this, go further and say that pigment in simple solution in the blood gives the direct test, while pigment combined as with protein gives the indirect, but that the combined state is not due to the hepatic or intrahepatic origin of the disease but to certain factors inherent in the blood itself that permit the combination.

In other words, bilirubin being a pigment in simple solution is quite capable of staining the tissues more or less persistently, and the blood protein merely takes up the stain and holds it. This staining depends in part on the time and the intensity of the process; it may be modified by bile salts or by other substances in the blood, and it can be reproduced in vitro. At most, the van den Bergh test is a good substitute for examining the urine for bilirubin, only it is much harder to do.

In a recent article by Schiff,[1] describing one of the most extensive applications of the tests, there was apparently no exception among 327 normal persons and patients that the van den Bergh direct reaction occurs with jaundice and bilirubinuria and that the indirect reaction occurs with jaundice with no bilirubinuria, regardless of the pathogenesis of the jaundice. Schiff also reports the direct test—supposed to be due to obstruction of ducts—in all his jaundiced lobar pneumonia patients, in all his catarrhal jaundice patients and in eight out of sixteen patients with cirrhosis of the liver.

Time ought to settle the value of the van den Bergh test; but now that textbooks are including it for the sake of being complete, a long time may be needed. Furthermore, I think it is no exaggeration to say that the newer physiology of bile pigment and liver function written by Mann and his associates, brilliant as it is, has not yet been usefully applied in the clinic to the first question of jaundice; namely, the diagnosis of obstruction.

The third course mentioned—the study of the distribution of bile pigment to see whether stoppage of the ducts alone could explain the jaundice—requires relatively simple laboratory methods. Their very simplicity has impeded their popularity, but the icteric index and the examination of duodenal contents and of feces are simple and of good repute when properly interpreted.

The icteric index is little disturbed by other pigments such as carotin, for carotinemia rarely occurs to a significant degree. With the simple expedient of clearing cloudy specimens by extraction with acetone, they can all be read accurately and easily.

The examination of duodenal contents for biliary pigments is enormously valuable, and so is the examination of feces and urine. Although no satisfactory quantitative methods for duodenal contents or feces and urine are available, quantitative measurements of blood together with qualitative tests on the excreta give evidence about the distribution of bile pigment—such evidence as is necessary to a diagnosis of obstruction. These methods together with certain facts about the physiology of bile pigment make up a useful laboratory study of jaundice, quite in contrast to tests.

What are the main facts in bile pigment physiology that must be considered? Bilirubin is formed in the bone marrow and in the liver, probably in fairly constant amounts,[2] perhaps increased with the total metabolism but not appreciably diminished by any known physiologic process. Bilirubin is present in small amounts in circulating blood, in combination with protein. In this state it does not pass through the kidney to appear in the urine. Whenever there is sudden and marked increase in bile pigment formation, such as occurs in transfusion reactions with hemolysis, there is diffusion of pigment into the tissue (jaundice) and filtration through the kidney (bilirubinuria). Also, whenever there is not prompt passage of pigment through the liver, such as in arsphenamine poisoning of the liver, there is jaundice and choluria. Likewise, when there is good enough filtration, but stoppage of the ducts, there is jaundice and if the blood saturation is great enough there is choluria. When blood and tissues have been stained they remain stained an appreciable length of time according to the degree, and I think somewhat according to the length of time the staining has existed. When blood proteins have combined with pigment, that pigment does not appear in the urine. Bilirubin is excreted by the epithelial cells of the liver, stored in the gallbladder by a process of concentration, or drained into the intestine, where pigment is quickly changed by bacterial action to urobilinogen, a part of which is absorbed by lymphatics and portal vein, a part is degraded further to unrecognizable form, and a part is excreted in the feces as urobilinogen.

[1] Schiff, Leon: Serum Bilirubin in Health and in Disease, Arch. Int. Med. **40**: 800 (Dec.) 1927.

[2] McMaster, P. D.; Broun, G. O., and Rous, Peyton: Studies on Total Bile, J. Exper. Med. **37**: 395 (March) 1923.

Although all these facts are now commonplace and the icteric index and other methods have been more or less in vogue, it is remarkable how little information about obstructive jaundice has accumulated—information about what happens when the ducts are stopped and bilirubin accumulates. Such knowledge as could be had from the icteric index, duodenal contents and feces in relation to colic would be of great value in many of the clinical problems that arise.

It seems to be customary that, when it is known that a patient has stoppage of the ducts, no further study of his distribution of bile pigment is made. Valuable studies have been made by Rous,[3] by Walters[4] and by others, but elementary facts about stoppage are not now available. How quickly after stoppage in man does the icteric index rise? How long before choluria develops? How long before the stool is clay colored? Will the icteric index reach a level and remain so; that is to say, will the kidneys be able to keep jaundice at a constant level, and if so at what level? Does complete stoppage inhibit the formation of bile pigment? Does icterus ever become so severe as to stain duodenal contents by diffusion through mucous membranes? When obstruction is relieved, how quickly does the index fall? How quickly does the urine clear? How does intermittent obstruction affect the distribution of pigment? How does partial obstruction affect it? In proposing these queries, I am assuming that stoppage can be accurately gaged as to onset, completeness, intermittence and relief.

Such knowledge about stoppage is often not certain; but when it is, few accurate observations are recorded, for it is the custom of surgeons to operate and relieve stoppage, not bothering about the jaundice once its significance is clear. Consequently there is some knowledge about the distribution of bile pigment, but there is not the exact information necessary to an understanding of the patient whose stoppage is within the liver itself, or whose stoppage is associated with disease of the liver as well.

It is well known that there is a reciprocal relation between bile in the duodenum and bile in the blood—which is another way of saying that acholic stools occur simultaneously with jaundice. It is also known that when the storage function of the gallbladder is intact there is a brief delay in the onset of jaundice. But in the main the problem in each case is decided by the history of colic or by feeling the enlarged gallbladder. This is a sure enough way usually, when such information is at hand, but without it there is no way to get the facts.

The differentiation between painless jaundice due to stone and catarrhal jaundice is often impossible; likewise the recognition of arsphenamine jaundice when there has been abdominal pain. No progress in the problem is in sight, if all the measuring and testing are done in the obscure and doubtful cases. It is clearly the duty of the surgeon to write more about obstructive jaundice to aid in the problem. I see no help from the physician who seldom handles obstructive jaundice. I see no help from the physiologist or the biochemist. It is chiefly my aim in this paper to emphasize the value of methods as they now stand; viz., the icteric index and the examination of duodenal contents and feces, when applied to clear-cut and uncomplicated obstructive jaundice. With better information of the common, one can hope to deal with the uncommon. Instead of the surgeon receiving help from the physician in the problems of jaundice, it is clearly the duty of the surgeon to furnish this help to the physician.

PHYSIOLOGIC DISTURBANCES INCIDENT TO OBSTRUCTIVE JAUNDICE

A REVIEW *

A. C. IVY, Ph.D., M.D.
CHICAGO

Medical history reveals that the problem of the jaundiced patient is an old one. It occupied a prominent place in ancient Hebrew and Arabian medicine, and this symposium signifies that the problem is not yet solved. Although tremendous progress has been made in the surgery of obstructive jaundice, the same cannot be said regarding the physiologic disturbances. Considerable work has been done and progress made, but the problem has not received the attention it deserves.

The physiologic disturbances incident to obstructive jaundice are too numerous to list and to discuss even briefly in a short review. One can consider only those disturbances which appear to be the most important in the light of present knowledge. That the physiologic disturbances are numerous and complex is to be expected when one considers that bile retained in the biliary passages not only may pass into the blood and thus influence many organs but also may disturb the functions of the liver and the gastro-intestinal tract. Even if bile were not toxic in itself, one would expect disturbances due (*a*) to the effect of excessive biliary pressure on liver function; (*b*) to reflexes excited by excessive biliary pressure; (*c*) to the absence of bile in the intestine, and (*d*) to the effects secondary to these changes.

CAUSE OF DEATH IN JAUNDICE

Toxicity of Bile.—Bile has been thought to be toxic since the beginning of medicine; it is now an established fact. All experimenters agree that adequate quantities of sterile bile introduced intravenously cause death. But there is a surprising lack of agreement as to what constituent of bile is toxic, or most toxic. A glance at table 1 shows that three constituents of bile have been suspected of being toxic; namely, pigment, bile salts and cholesterol. It can be considered as established that cholesterol in the amounts present in toxic doses of bile is not the toxic agent. What the effect of the hypercholesterolemia associated with jaundice might be over long periods of time is another question. It is well established that bile salts in adequate amounts are cytolytic and toxic, and the majority of investigators attribute to these the toxicity of bile. The data on which the claim of high toxicity of the bile pigments[1] is based can be criticized in that the pigments used were impure and the method of administration questionable. The more recent work of Horrall and Carlson[2] and of Still,[3] in which pure bilirubin and bile salts were used, shows that bile salts are toxic and that bilirubin spectrophotometrically identical with circulating bilirubin is not. The existence of some unknown toxic agent in bile is improbable, since the experiments of these investigators indicate that the toxicity of bile salts is sufficient to account for the toxicity of bile. However, the work of Meltzer and Salant,[4] Bunting and Brown,[5] and Greene and Snell[6] indicates that whole bile may be more toxic than its two major constituents.

[1] Merck's Report **28**: 13, 1914.

Even though the bile salts are chiefly responsible for the acute toxicity of bile, it does not follow that the passage of bile salts into the general circulation in increased amounts is the sole cause, or even a cause, of the disturbances incident to jaundice. One must first be able to answer the following questions: In jaundice do the bile salts accumulate in the blood and tissues sufficiently to be toxic? And, what is the effect of a prolonged but not acutely toxic increase in circulating bile salts? Following the same logic, bile pigments may not be acutely toxic, but the gradual accumulation of bile pigment in the tissues and its prolonged action on them as occurs in jaundice may produce disturbances.

The earlier observers[7] believed that in obstructive jaundice bile acids were increased in the blood, lymph and urine, but they were puzzled by the small amounts found. For example, Bischoff[8] found a maximum of only 0.34 Gm. of bile salts eliminated in the urine in twenty-four hours in a deeply jaundiced patient, and Hoppe-Seyler[8] had to use 30 liters of urine from a jaundiced patient to obtain a positive qualitative test. More recent observers,[9] using better methods, have verified the earlier work and found that during the first week or two following obstruction the blood and urine bile acids increase but thereafter fall to normal levels. It has been suggested by some[10] that in jaundice the blood destroys the bile acids. Weintraud[11] offered an explanation which has more in its favor; namely, that the liver ceases forming bile acids. This is also suggested by Brakefield and Schmidt[9] and Snell, Greene and Rowntree.[9] The latter investigators have shown that serum bilirubin also tends to decrease in the later stages of obstructive jaundice, probably because of a decrease in production,[12] which may be associated with the anemia.[13] As jaundice progresses the "bile intoxication," as judged by the bile acid and pigment content of the blood, becomes less. It appears, then, that death from obstructive jaundice may not be due to the passage of bile into the circulation in toxic amounts. No one has injected bile continuously in small subacute toxic doses over long periods of time to observe the effect. But there are data bearing on the relative toxicity of bile intravenously, taking into consideration the time of injection and the daily output. Two grams of bile salt given in one minute to a 10 Kg. dog is generally lethal, but given throughout one hour does not prove fatal; but 4 Gm. in one hour is fatal.[14] These amounts are about one-half the normal twenty-four hour output.[15] Therefore, if injected slowly, the normal dog can eliminate one half of its total twenty-four hour output of bile salts within two hours.[6] The jaundiced dog also eliminates bile salts but not as rapidly as a normal dog, as might be expected.[16] The foregoing doses produce a concentration of bile acids in the blood of from three to five times that found at the highest point of blood bile acid following common duct obstruction. This suggests that bile salts may not accumulate in the blood in jaundice sufficiently to be toxic. Further, it cannot be said that the presence of a high bile acid level for several weeks leads to irreversible fatal toxic changes, since long standing obstruction, when relieved in the human being, results in a return to normal health. It is true that the injection of 5 cc. of sterile gallbladder bile per kilogram intraperitoneally causes a fatal peritonitis in dogs and rabbits (0.5 cc.).[17] But this is a large dose and the cytolytic action of bile on the peritoneum may set free toxic substances that act coincidentally with the absorbed bile salts.

The effect of an Eck fistula on jaundice is interesting and has a direct bearing on the question at hand.[18] The Eck fistula liver produces only about one-half the normal amount of bile, and when biliary obstruction is produced in such animals jaundice is very slight; or, if jaundice is present, an Eck fistula markedly relieves it and, according to Mathews,[18] prolongs the life of jaundiced animals. These data might be interpreted as showing that, the smaller the quantity of bile being formed, the less bile there is to overflow from the liver into the blood and to produce toxic effects. But it might also be interpreted as showing that, the smaller the quantity of bile being formed, the less the acute pressure and local toxic effects in the liver.

These observations strongly suggest that a patient in whom the liver is functionally deficient to begin with will withstand jaundice longer than one with a normal liver.

Liver Damage.—It is well known that anatomic liver damage occurs in obstructive jaundice. The pathologist speaks of "icteric necrosis,"[19] "biliary infarcts"[20] and biliary cirrhosis. These changes have been observed in various animals by Rous and Larimore[21] and by Snell, Greene and Rowntree.[9] The former investigators have pointed out that the liver changes following biliary obstruction are essentially the same as those which occur in glands in general when their excretory ducts are obstructed. Obviously, therefore, if the anatomic changes are sufficiently extensive, one should expect disturbances in liver function.

As might be expected, the literature on disturbances of liver function due to obstructive jaundice is contradictory. Weintraud,[10] reviewing the older literature, stated that obstruction "to outflow of bile hinders the storing of glycogen in the liver." More recently, Snell, Greene and Rowntree[22] found the fasting blood sugar level to be normal but the fructose tolerance to be decreased. Weintraud[10] concluded that urea formation is rarely affected, but more recently it has been found in animals that the blood urea level falls to rise later because of a terminal renal insufficiency.[22] The retention of bromsulphalein has been found to be persistent throughout experimental jaundice,[10] as might be expected. Ascites is known to develop in prolonged jaundice in both man and dog.[23] These observations indicate that liver function in jaundice is disturbed; but a satisfactory answer awaits the discovery of a real liver function test.

The Lack of Bile in the Intestine.—Bile flow into the intestine seems to play an important if not a vital rôle. Dogs with complete biliary obstruction generally die in three months but occasionally survive six or seven months. Bile fistula dogs on a kitchen scrap diet generally survive only two months, but on a milk-carbohydrate diet they survive for from four to ten months and manifest marked abnormalities of the bone, purpura, anemia and pigment disturbances.[24] Whipple[24] reports that, if from 10 to 20 per cent of the bile flows into the intestine, health is normal. The same quantity of bile by mouth is beneficial but does not prevent a disturbance of nutrition. The constituent of bile that plays this important rôle is not known. By adding to the diet liver and bile[25] cod liver oil or ergosterol,[26] bile fistula dogs have been kept for more than a year. In man,[27] complete obstruction generally proves fatal in from four to six months, although there have been occasional instances of longer survival. Human beings with biliary fistula[28] apparently are less affected than are animals, some patients dying in ten months and others doing well for even a longer period of time. Proper dietary control is apparently a very important factor.

Bony disturbances, hemorrhages, disturbances of digestion and nutrition, decreased bile salt formation and anemia are phenomena common to both jaundice and lack of bile flow into the intestine.

It cannot be concluded, however, that the lack of flow of bile into the intestine is the cause of death in jaundice.

Terminal Nephritis.—Snell, Greene and Rowntree[22] observed in jaundiced dogs a terminal rise in blood urea due to renal insufficiency. Still and Carlson[23] also observed nephritis in their dogs. Horrall and Carlson,[2] following the injection of bile into the peritoneal cavity, observed an anuria which they explained as due to the fall in blood pressure associated with the intoxication. They further found that, on administration of sublethal doses of bile, albumin appeared in the urine for several weeks. Further evidence is required to ascertain what rôle a terminal nephritis plays in the cause of death in jaundice.

Summary.—I do not believe that the evidence at hand permits a positive statement as to the cause of death in jaundice. A summation of the foregoing factors is probably the cause, and one factor may predominate in one case and another factor in another case. The fact cannot be avoided that bile in adequate doses is lethal, but it is not known that the amount of bile that actually gets into the blood stream in jaundice will prove fatal. It is known that jaundice affects the liver, but it is not known that acute liver insufficiency occurs in jaundice. It is known that the absence of bile from the intestine leads to marked disturbances of nutrition and metabolism, but it is not certain that such changes per se will prove fatal. The patient suffering from prolonged jaundice presents a picture that results from the failure of a number of physiologic mechanisms.

THE HEART IN JAUNDICE

Much has been written concerning the bradycardia which is said to occur commonly, but not always, in the jaundiced patient. Some well known internists[29] have failed to observe it. According to Osler, it occurs only during the early stages of jaundice or only during the time at which there is accumulation of bile salts in the blood, which I believe is a significant observation. Windle[30] found bradycardia present in young people having catarrhal jaundice but not in the majority of cases with obstructive jaundice. Buchbinder[31] observed it in early obstructive jaundice in puppies but not in adult dogs. Apparently the "younger" the vagocardiac mechanism, the more sensitive it is to the early effects of jaundice, which is sufficient to explain the discrepancies in the literature.

Given a sensitive mechanism, what causes it to react? There is ample evidence showing that bile or bile salts in moderate doses increase vagal inhibitory tone and that atropine or vagus section abolishes the bradycardia.[32] (In larger doses the intracardiac ganglions and the cardiac muscle are injured.) This means that the causative factor is operating either on the vagus center or on the nerve endings. In jaundice, vagal tone can be increased either by reflexes caused by distention of the biliary passages[33] or by the increased bile salt level of the blood in early jaundice. In the marked cases of bradycardia, both mechanisms are probably operating. Another factor that must be kept in mind is the low calcium content of the heart reported by King, Bigelow and Pearce,[34] which is questioned by Buchbinder,[31] and the alleged decrease in "utilizable" blood calcium to be discussed later. Also Finsterer[35] and

Ricciuti [36] report that liver injury may cause bradycardia.

The depression of blood pressure and the feeble pulse which occur after prolonged jaundice are explained by Horrall and Carlson [2] as being most probably due to malnutrition rather than to the toxic action of bile salts.

BLOOD CLOTTING AND CALCIUM LEVEL

In spite of the skepticism that is occasionally expressed, it can be considered as established that in certain cases of obstructive jaundice there is a tendency to hemorrhage. The factors responsible for the variation from patient to patient are not known. The duration of the jaundice is reported to be a factor by Lee and Vincent.[37]

In spite of the large amount of serious work done, the cause of the tendency to hemorrhage in jaundice is not understood. It may be due either to some disturbance of the organic clotting elements or to a functional deficiency of calcium causing delayed coagulation or an "unfirm" clot, or to fragility and lack of contraction of the blood vessels. (Duke's bleeding time should be determined as well as the clotting time.) All the various clotting elements have been suspected as being at fault—thrombin formation and available thrombokinase,[38] fibrinogen [39] and fibrin formation.[40] The greatest amount of study has been devoted to blood calcium, since it is known to play an important rôle in clotting and since a disturbance of calcium metabolism is present in prolonged jaundice.

The summary of the literature shown in table 2 demonstrates that there is no agreement as to either the quantity or the quality of the blood calcium in jaundice. This lack of agreement may be due to defective technic or to unknown variable factors. The results of Buchbinder [31] show that age is an important factor, since puppies showed a definite decrease in serum calcium and disturbances of bony structure whereas little or no disturbance occurred in adult dogs. The most recent and careful work of Snell and Greene [41] shows that there is no correlation between total or diffusible serum calcium, bilirubin content and coagulation time in jaundiced animals and man. It is generally maintained without proof that diffusible calcium is more readily metabolized. But Snell and Greene find that calcium chloride can be given intravenously and the coagulation time reduced without affecting serum bilirubin, serum calcium and diffusible calcium. Vines [42] reports that ionized calcium is not necessary for clotting. Cantarow, Dodek and Gordon [43] state that parathyroid extract hastens coagulation in jaundice, but Zimmerman [44] was unable to detect any change, even though he observed an increase in the blood calcium. That there is some functional deficiency in calcium metabolism is indicated by the bony changes in jaundice,[31] by the greater tolerance of the jaundiced dog to intravenous calcium,[45] and by the decreased effectiveness of parathyroid extract in parathyroidectomized dogs with jaundice;[46] but it does not follow that delayed clotting is due to a functional deficiency of calcium even though an injection of calcium does hasten coagulation. The literature does not teach how calcium administration in jaundice hastens coagulation, which I know from personal observation it does in some cases. Nor is the cause of the disturbance of calcium metabolism known; but the literature explains it as due either to decreased absorption and increased elimi-

nation or to a combination with bilirubin, or to the use of calcium as a "detoxifying" agent.

It should be pointed out that intravenous therapeutic doses of calcium rapidly disappear from the blood,[47] and the effect on coagulation may be transitory.[48] Overdoses must be avoided because of possible damage to the kidney and heart.[45]

SUMMARY

In obstructive jaundice there exist a number of failing physiologic mechanisms and it is not known which one is primarily concerned. The fundamental nature of the reactions involved in producing the physiologic disturbances is not completely understood at present. The literature indicates that a carbohydrate diet with milk and cod liver oil and calcium administration are worth while therapeutic procedures in this condition. The fact that the problem is being actively attacked by several groups of investigators augurs well for the future of the understanding of physiologic disturbances in jaundice.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. JUDD AND MARSHALL, PAYNE, BLANKENHORN AND IVY

Dr. F. C. Mann, Rochester, Minn.: Bile pigment is important to the clinician because it gives the sign of jaundice. To the physiologist it is the least important of the biliary constituents. So far as is known it is wholly an excretory product, a part of the hemoglobin molecule which cannot be used any more. It is known to be formed from the hemoglobin that is taken from the red blood cell. No other constituent of the blood from which it can arise is known. It is known that certain extrahepatic cells, which Aschoff calls the reticulo-endothelial cells, form it. It has never been proved that the polygonal cells form it. I would not mention the van den Bergh test except for its presentation by Dr. Blankenhorn, but I suggest that the van den Bergh test, direct and indirect, does mean something in regard to bile pigment. I shall cite one series of experiments that Dr. Bollmann and I have performed. In a dog of which the common bile duct is ligated and the gallbladder removed, bilirubinemia begins to develop and can be determined spectrophotometrically within fifteen minutes. After six or eight hours the plasma, which was colorless before operation, is yellow, gives a definite reaction, and is measurable by the van den Bergh test. If the liver is removed after bilirubinemia has developed, the curve of development of bilirubinemia does not change. As measured by the van den Bergh test or with the spectrophotometer there is a constant increase of bilirubin in the blood and removing the liver does not change the rate of its development, but the amount of bilirubin which responds to the direct method does not increase. In other words, all of the increased amount that is found after removal of the liver gives only the indirect reaction. This, to me, would imply rather conclusively that the liver does something to the bile pigment, even though most of it is not formed within it. For fear that I might be thought to be too much in disagreement with Dr. Blankenhorn concerning the van den Bergh test, I should also report the fact that there are some species of animals which never give a direct van den Bergh reaction, even though the bile is taken directly from the hepatic or common bile ducts.

Dr. Onis H. Horrall, Chicago: The cause, mechanism, significance and the physiologic and pathologic effects of jaundice have been investigated for many centuries, but not until the beginning of the nineteenth century have the particular substances in bile been investigated. Bilirubin has been accused as the offending substance, and accordingly the present classification of jaundice has been based on the bilirubin content of the blood, and the kind of bilirubin according to the van den Bergh test. Brulé and the French school have pointed out that bilirubin and bile salts vary in jaundice, and they speak of dissociated jaundice. Certainly the toxic symptoms in jaundice cannot all be attributed directly to bile or to its acids. Jaundice is a complex problem. Numerous systems are disarranged, as the digestive, the circulatory, the urinary, and even the nervous, either primarily or secondarily. Intravenous injections of bile have been compared with obstructive jaundice. But here little is known of the amount of bile acids in the blood stream, nor is it known how they act on the different cells. As recently shown, the bile pigments are not entirely of hepatic origin. May not the bile acids be the products of the metabolism of the body cells? Thus the study of the bile acid content of the blood and body tissues may give some clue to the actual pathologic condition. I believe that, as soon as a very sensitive specific test for toxic bile acids is discovered, it will be possible to classify jaundice on a more workable basis. The use of dehydrocholic acid, intravenous or by mouth, may modify the course of jaundice.

Dr. Joseph S. Diamond, New York: I wish to correct the impression Dr. Blankenhorn has given regarding the inability of differentiating the obstructive from other types of jaundice. The differential diagnosis between the hemolytic type and the others offers no difficulty. The condition, however, which concerns every one is to know, when one is faced with a case of jaundice, whether it is due to obstruction, requiring surgery, or to an hepatic disease, requiring merely medical attention. Dr. Blankenhorn was pessimistic about present knowledge and could not mention any clinical test to help in such differentiation. He spoke briefly of urobilinogen, from the physiologic standpoint. He has not stated, however, that the daily studies of the amount of urobilinogen in the urine in jaundice will quickly give information as to the type of jaundice one is dealing with. In the obstructive type no bile can enter the intestinal canal; therefore no urobilinogen will be found in the urine, because urobilinogen is a pigment derived from the bile, being oxidized in the large bowel. On the other hand, in the catarrhal or toxic jaundice there is no obstruction in the common duct. The old theory of a mucus plug in the common duct derived from an ascending gastroduodenitis has been proved pathologically incorrect. Toxic or catarrhal jaundice must be regarded as a disease of the liver itself, a parenchymatous change in the liver cells. There is no obstruction in the bile passages, and bile is found in the intestine. The urobilinogen formed is brought back to the liver and there the diseased liver, being unable to utilize it, shunts the urobilinogen into the general circulation, whence it is eliminated in the urine in large amounts. The increased output indicates the existence of toxic hepatitis. In other words, it is a medical type of jaundice which should be left alone. A test of value described by Wallace and Diamond consists of the addition of Ehrlich's aldehyde reagent to freshly voided urine. A red coloration is obtained, varying in intensity with the amount of urobilinogen present. Normally only minute traces are found. In obstructive jaundice none is found, while in catarrhal jaundice a deep, dark red develops. In a case of jaundice, the urine should be tested daily and if it is persistently negative for urobilinogen one may regard it as due to obstructive causes, requiring surgery, while in the catarrhal jaundice it will increase daily with the progress of the disease and is of good prognostic omen.

Dr. M. A. Blankenhorn, Cleveland: I am aware of Dr. Wallace's and Dr. Diamond's studies in urobilinogen in urine and feces and have applied them for a long time. I still am a bit pessimistic in regard to these tests. I have found frequently that if the test is applied during the obstructive period (and there is an obstructive period in catarrhal jaundice in which urobilinogen is wanting from the urine) there will be an error in diagnosis. If the test is applied next day when conditions have changed somewhat, one immediately switches to a different type of jaundice. The thing I would emphasize, lest I appear to be quibbling, is that the problem must be considered as kinetic and not static, and that frequent observations must be made during the course of the disease.

THE MENACE OF MENTAL FACTORS IN BODILY DISEASES *

CORNELIUS C. WHOLEY, M.D.
PITTSBURGH

Medical and surgical conditions are often imitated and exaggerated by mental causes. This circumstance constitutes a menace in diagnosis and treatment. Stevenson[1] recently found in a large medical clinic that 19 per cent of the patients who came to the gastro-intestinal specialist had severe emotional problems, and that in only one fourth of the cases were mental or emotional disturbances absent. In 16 per cent of the children brought to the pediatric clinic, emotional factors arising in the home were responsible for the disorders in the children.

A vast amount of evidence has accumulated to show that mental conflicts and emotional disturbances upset the normal physiologic functions of the vegetative or sympathetic system. This system, as is known, regulates secretion, circulation, digestion and respiration. If it is disturbed, functional disability takes place in the viscera associated with these functions, such as kidneys, heart and stomach. When this functional upset persists, in time it may become organic. Now, if such causal relationships between mental and bodily functions are borne in mind and dealt with as a matter of routine, along with toxic, infectious, metabolic and other causes of ill health, the menace of mental factors in medicine could be largely eliminated.

I am concerned in this discussion mainly with the bodily disturbances associated with the psychoneuroses —hysteria, neurasthenia and anxiety states. Similar pseudo-organic maladies are encountered also in the true insanities, especially when depression exists, and they generally involve the digestive tract. But the mental symptoms in these patients are usually so pronounced as to indicate without question the psychic origin of the symptoms and generally lead to early institutional care. Broadly speaking, the cases cited in this paper may all be regarded as arising on a background of hysteria, fabricated through both hereditary and environmental influences.

The first case I shall discuss presented offhand a clinical picture of change in the gallbladder which ordinarily would call for surgical intervention. But on further investigation it was found that the symptoms were entirely on a mental basis.

REPORT OF CASES

Case 1.—An Italian girl, aged 14, referred by her family physician because of his inability to discover any convincing evidence of gallbladder disease, presented the usual clinical symptoms of gallstone attacks. She had complained for six months of symptoms characteristic of cholelithiasis. There had been almost constant nausea and at times vomiting. Lately she complained of pain in the right hypochondrium, which during the past three weeks had occurred in paroxysms with nausea. Pain was increased by food. There was dizziness and headaches at times with the attacks of pain and nausea. Pain radiated to the back and right shoulder.

The symptoms continued to become more aggravated until finally operation was considered. In the hospital, however, a thorough examination again failed to reveal any evidence of diseased gallbladder. Roentgen and fluoroscopic examinations were negative. There was no rigidity over the abdomen; no jaundice; no clay-colored stools; no occult blood; the pulse was between 80 and 90. At this time there was a slight elevation of temperature for the first time during the illness.

The patient was a stout, healthy looking girl. She seemed anxious and fearful during the examination. Neurologic examination brought out no evidence of any organic nervous disease. Her manner and her overreaction to all reflex stimuli strongly suggested hysteria. The excessive anxiety of her mother, who hovered near by and vividly related her daughter's many symptoms, suggested plainly a neurotic background.

The case became intelligible in the light of the following mental and emotional factors:

The patient was the youngest of five children. Her bowels were badly constipated when she was an infant. At 15 months of age she had unconscious spells lasting from three to five minutes at a time. They occurred sometimes daily or again only once a week and were not accompanied by convulsive movements, or by any other signs of epilepsy. They continued until her fifth year. At her eleventh month, she would roll her head rhythmically from side to side for two or three days at a time. At 10 years her appendix was removed. It should be noted that the appendicitis was not acute. I was unable to learn whether the appendix was diseased in any way. She talked at 18 months and walked at 2 years. Her history was then uneventful until the present illness, which set in six months before I saw her.

Turning to the mother, I quickly discovered that a morbid emotional relationship existed between her and the daughter. The mother herself had suffered from gallstone attacks during the pregnancy with and since the birth of this youngest child. She was unusually devoted to the child and kept watch over her to an extraordinary degree. The two were always inseparable and when the child grew older she nursed the mother through many true attacks of gallstones. Operation cured the mother. Six months later the daughter settled into her own seeming gallbladder attacks.

Following the mother's convalescence from her operation, the girl began having discomfort in the lower left abdominal region, probably due to constipation and innocent except for the ready mental soil prepared by her intimate sympathetic life with her mother through the latter's gallbladder sufferings. Then the girl began having symptoms similar to those presented by the mother during her gallstone attacks. The distress shifted to the right side and a perfect duplicate of the mother's attacks was soon evolved. The mother gradually became convinced that the girl was affected as she had been. She had little difficulty in convincing the daughter that this was a fact. She decided that prenatal influence had destined the child to her own infirmity. She finally became obsessed with the idea that nothing but an operation would cure the girl, since operation had been her own salvation.

In the light of the foregoing data, the youth of the patient, and in the absence of physical and laboratory confirmation, the case was diagnosed as unquestionably one of major hysteria. The girl was identifying herself with the mother and had gradually taken on all of the mother's gallbladder symptoms.

In order to corroborate this diagnosis, complete isolation of the girl from the mother was carried out for two days, under great protest on the part of the mother. During these two days, the symptoms entirely disappeared. The mother took the girl home and all symptoms immediately reappeared. It was impossible to convince the mother that no operation was necessary and that the girl might be cured if the mother would consent to be separated from her. The continuance of the symptoms and the demands of the mother for operation finally brought about a laparotomy. A normal gallbladder was revealed. The girl has remained free from the gallbladder attacks for six months, certainly because of suggestions of cure she received following operation. However, she has complained almost continually after the first month, of abdominal distress At times, the complaints are acute and accompanied by slight rise in temperature. Her visits to a physician are as frequent as ever. She is likely to follow a course of chronic invalidism. Her neurosis has not and cannot (because of family) be dealt with. To it has no doubt been

[1] Stevenson, George: Why Patients Consult the Gastro-Enterologist, J. A. M. A. 94:333 (Feb.1) 1930. Emerson, Haven: The Magnitude of Nervous and Mental Diseases as a Public Health Problem, at the first international Congress for Mental Hygiene, Washington, D. C., May 6, 1930.

added some degree of organic disorder. She has been caught in a vicious circle whose weakest arc—the mental or neurotic—is least accessible to therapy.

Case 2.—*History.*—A woman, aged 48, was referred to me because of the sudden onset of violent occipital headache, dizziness and vomiting. These symptoms had come on suddenly on arising, the day before I saw her. She said the back of her neck felt as though she had been suddenly hit with a club. She had been referred because her symptoms suggested brain tumor or meningitic involvement.

The patient was well nourished. She held her head turned to the extreme left, with an expression of anxiety and pain. Examination was difficult because of nausea, which was increased on exertion, and because the patient declared that if she turned her head to the right, even to a slight degree, she was immediately beset by the most intense vertigo. She said, "The room immediately whirls to the left, and I quickly follow, turning in the same direction."

I found, however, that her pupillary reactions presented no anomalies, though the pupils were moderately dilated and reacted poorly to light, the left showing a better reaction. Ocular movements were good but there was a slight internal squint of the left eye, which had been present from childhood. The ocular disks were normal. There was no rigidity of the neck, no deafness, no adiadokokinesis. Laryngeal and pharyngeal innervation were normal. The right elbow jerk was a little more active than the left, both being somewhat plus. The knee jerks were normal. Babinski's sign was absent. The temperature was normal, the pulse 80. Sensation was normal; the blood and urine gave negative results to tests. The blood pressure was 147 systolic and 90 diastolic.

Because of the absence of physical or neurologic signs of any acute inflammatory condition, and the absence of any definite indication of organic intracranial disturbance, and because the patient's vomiting and vertigo were already less disturbing, an expectant plan was followed after administering hypnotics and reassuring the patient. This plan was further justified by the patient's reaction, which seemed to present an emotional element. This fact suggested a doubt as to the organic origin of her symptoms. She overreacted, and her expression of pain was not convincing as is that seen in true organic cases.

Spinal fluid and roentgen examinations were withheld, and when the patient's history came to light, it gave further justification for following a waiting plan of treatment. She grew better rapidly. She was eating comfortably twenty-four hours after admission to the hospital. She had to be very careful about moving her head because of the vertigo, but this also gradually disappeared and she could move about the room freely at the end of ten days. At the end of four weeks she went home entirely free from all symptoms and has remained so now for eight months.

Emotional Background.—At the age of 15, this patient "lost her eyesight." Regular physicians had failed to cure her, but her sight had been restored after a few visits to an osteopath. She had married happily at 21, longed for children and had had great disappointment when her first child died at the end of nine days. A second child, born a year later, lived but was mentally defective, having to be placed in an institution for the feebleminded. She said this experience was the "worst of her life." She had seemed, however, to readjust herself fairly well. Her home was pleasant; she had many friends and a devoted, tactful husband. Her continued yearning for children was rewarded after sixteen years by the arrival of a boy, now 6 years of age. Her solicitude and affection for this last child was of course intensified by the memory of her previous sad experiences with children.

When I inquired about events immediately preceding the present illness, I found that six months earlier she had fallen, striking the lower end of her spine, which had "upset her nerves for several weeks." Following this, an automobile trip through Yellowstone Park left her pretty well exhausted on returning home.

Then her boy started to school and it was noticed that she became unusually active. She said she could no longer sit at home quietly as she used to. She missed the boy. She took on numerous social and church interests (compensatory activities). Two months before her present illness, it was decided that the boy's tonsils should be removed. She became extremely anxious. She could not keep the thought of the possibility of losing him out of her mind. The day for operation was set and the mother's anxiety increased. It is important to bear in mind the patient's emotional state at this time, and particularly the details of the next scene, as this appears to have determined the clinical symptoms she later imitated.

She was allowed to see the boy in his room immediately on his return from the operation. He was still under the anesthetic. His head was turned to the left over a sputum pan because of his nausea, vomiting and bleeding. (The mother's symptoms on admission: head turned to left; vomiting.) She "felt sure he was going to die." Ten days later, she had a spell of nausea and at this time received news of the death of a very dear friend. At the funeral she was again nauseated. The evening of this funeral a large celebration for her silver anniversary took place. She had to be excused from the festivities because of nausea and vomiting. The next day, one of the friends who had attended the celebration died. This event caused still further shock. From that time until the acute onset of her present symptoms, she was restless, anxious and nauseated with slight vertigo at times. This period represents the preliminary or incubation time of the neurosis, though preceding events prepared the soil for the final break.

Time will not allow a detailed analysis of the relationship of the patient's later acute illness with the incidents just cited. They centered around her 6 year old boy and his operation. The entire and rapid disappearance of all her symptoms left no doubt, however, that they were emotional or psychogenic in origin. She passed into her psychoneurosis at the time of the boy's operation. The death of two friends while she was still in this emotional state aggravated her neurosis and it finally fashioned itself definitely after the image of her child with his head turned to the extreme left, vomiting—the picture presented by the patient on admission to the hospital. In such cases of overwhelming sympathy and emotion, a person may identify himself with another's suffering and may imitate all the evidences of such distress. In this case, the vicarious suffering occurred in an exaggerated degree.

The patient was rendered especially vulnerable by the chain of circumstances both preceding her son's operation and immediately following it. She had been extremely anxious as to the outcome of the operation and had been subjected to the shock incident to the deaths of two close friends. The vertigo was an exaggeration of slight vertigo experienced with the mild vomiting attacks that had occurred previous to the serious acute symptoms.

The case is intelligible in the light of such causative factors and is to be classified as an anxiety psychoneurosis with the passing over of psychic impressions into bodily manifestations—the so-called hysteria conversion phenomenon.

That this patient was predisposed to react in an hysterical fashion to overwhelming circumstances was indicated in the fact of her lost eyesight at the age of 15, restored by a few osteopathic treatments. She represents an extreme instance of how bodily symptoms of serious disease conditions can be taken on, or initiated through purely emotional causes. In this instance, the symptoms imitated those of an acute inflammatory meningeal irritation or brain tumor.

Case 3, in contrast to the previous two in which surgical problems seemed to the fore, presented symptoms apparently indicating medical therapy.

Case 3.—A woman, aged 40, had been bedridden for twenty years. I first saw her ten years ago. Her physician described her then as having neuritis and as addicted to opiates.

She had been an invalid since the death of her mother when she herself was 18 years of age. She was the eldest of four children, there being a sister and two brothers. The family was remarkable for the devotion that existed among its members. The father had died some years previously and this had served to increase the affection and mutual dependence of the surviving members on one another.

When the mother died, after a period of invalidism, the children displayed an unusual degree of grief. The patient whom I was asked to see seemed inconsolable. She made incessant visits to the mother's grave. She did not sleep and ceased to take part in the household affairs. Finally she began to complain of digestive disturbances and, six weeks after her mother's death, took to her bed. There she remained until the time of her death, twenty years later. It was about midway in this bedridden invalidism that I first saw the patient.

Her complaints at first centered about her digestion. Nausea appeared and occasional vomiting. She became emaciated and complained of weakness. Her sister became her constant companion and nurse. The greatest concern was shown over her complaints and symptoms; her illness became the paramount interest of the family. The pathetic story of this attractive young woman's invalidism gradually captured the sympathy of a wide circle of relatives and friends. Her home became a sort of shrine. Church societies and women's organizations to which she had belonged vied with one another in expressions of sympathy on all anniversary and holiday occasions.

At the time of my first examination, the girl was greatly emaciated. Her ten years' illness with all its elaborations had become a neighborhood institution. She kept her eyes closed most of the time during my early visits, appearing to have a marked photophobia. At times, however, I discovered her taking furtive glimpses of my actions when she thought I was not observing her. My visits had continued for several years before her eyes would meet my own squarely, and then but for a moment. Her conversation was usually rambling and at times incoherent, but during the later years of her illness she talked more freely, frankly, and often very intelligently. I was told that the patient had the most intimate knowledge of every detail concerning the affairs of each member of the household and her advice was sought by the family on all undertakings.

Her physician told me that suppositories of opium had already been administered rectally for several years. The dosage had gradually increased until about 5 grains (0.3 Gm.) of opium was being used daily. The narcotic had been begun following the earlier appearance of cramps in the abdomen. Severe neuralgic pains about the shoulders and chest seemed to necessitate increase of the drug. Gradually a swelling appeared in the right iliac region and constipation slowly reached the stage at which movements occurred only at intervals of between two and three weeks. The tense tympanitic tumor in the right iliac quadrant seemed to be a loop of bowel. The patient's reflexes were normal. There was no elevation of temperature. Her condition prohibited any thought of operation for the mass in the abdomen. Only few and specially prepared articles of food were taken, with frequent regurgitations.

During the ten years of my visits to this patient, the general set-up remained much the same. The invalid always detailed a pathetic story of misery and pain. If I came on her unawares, I often found her the center of a family gathering, apparently much interested. Her whole expression would change instantly on discovering my presence. Morphine by rectum was substituted for the suppositories. Her emaciation finally became extreme, circulation gradually failed, and she passed into a stupor and died from extreme exhaustion.

The patient was cared for throughout her illness by a devoted sister, whose life was sacrificed to the invalid in this mission. She strongly resented any suggestion that the patient might ever have assisted herself. Much of the family income was secretly expended in foolish "cures." The sister was in a critical state of depression for many months following the invalid's death and a brother did not resume work for two years after the funeral.

This case, though medical involvements appeared during the course, was primarily, and essentially throughout, one of major hysteria. The girl had been perfectly healthy previous to her mother's death. She had been reared in surroundings of excessive patriarchal family devotion and had never been allowed to develop anything beyond a childhood capacity for meeting life. She was entirely incapable of adjusting herself to the new situation occasioned by her mother's death. Her inadequacy soon transferred itself into physical invalidism and all her energies were transformed into the morbid self-centered hypochondriac state into which she settled, and from which she finally died after a slow bodily and mental decay of twenty years' duration.

SUMMARY

The cases cited represent somewhat extreme instances of the extent to which apparent surgical and medical syndromes may mask the real disease, where mental factors become converted into bodily expression.

Less pronounced conditions of invalidism and organic disturbance are frequently brought about wholly, or are exaggerated, by mental or emotional maladjustments.

Consideration of the mental situation in no way, either by inference or in fact, presupposes any slighting of the organic agencies of disease.

Evaluation of mental factors necessitates study of the emotional life of the individual, knowledge of the family setting and, at times, a readjustment of environment and domestic relations.

In "frozen" cases such as 1 and 3, "cracking up" the deadlock is well nigh impossible. Early detection of the morbid process, with firm and tactfully applied measures, will alone arrest the morbid infection.

Though in certain instances, as in case 2, it is conceded that a degree of organic change may be present, its relationship to the exaggerated symptoms could, at most, only be that of partly determining the sympathetic pathway to be followed by the neurosis.

121 University Place.

ABSTRACT OF DISCUSSION

Dr. Albert M. Barrett, Ann Arbor, Mich.: Dr. Wholey has directed attention to problems which in their nature have been most difficult to deal with, not only in diagnosis but also in practice. These difficulties lie in the complex interactions of psychic and physical factors, both in health and in disease, and the fact that psychogenic mechanisms can produce manifestations in the somatic or physical field closely resembling the symptoms of organic disorders commonly encountered in practice. The rigid lines of separation between what is organic or physical and what is functional or psychic are becoming less distinct in problems of physiology and clinical pathology, and concern is now found with the better formulation of how much is physical and how much is psychic. The lack of recognition of this interaction has often led to serious errors of diagnosis and treatment, which have occurred in all fields of medical practice. In a recent review of the past histories of 100 patients diagnosed in the Psychiatric Clinic, Ann Arbor, as psychoneurotic, it was found that 47 of these had previously undergone various surgical operations; 12 had appendectomies, 13 had some form of pelvic operation, and in 17 tonsillectomy had been performed. It would seem somewhat disproportionate that 47 of 100 patients whose fundamental disorder was psychic should have required such an amount of surgical treatment. This is further emphasized in the ineffectiveness of the operations on the illness or symptoms of the patients. But the problem of psychic causation and influences in diseases is far wider than the field of the psychoneuroses. How far reaching interrelations of psychic and physical are is revealed in recent knowledge gained in the field of constitutional pathology. It has been shown that certain types of psyche as manifested in the temperament are related to certain specific types of body formation. Cyclothymic temperaments seem to occur predominantly in those of pyknic type of body, and schizothymic temperaments are most frequently seen in those of asthenic type. There is also much evidence that certain somatic diseases tend to occur with greater frequency in certain specific types of somatic constitution and temperaments.

Dr. Meyer Solomon, Chicago: I wonder whether it wouldn't be better instead of speaking of "organic" and "nonorganic" or "functional" disorders to speak of "pathologic organic lesions" and "physiologic organic disturbances" of psychogenic origin. In emotion the bodily organs are shaken up and this shaking up is accompanied by chemical and metabolic disturbances and, no doubt, transient organic changes. Hence there are really physical organic changes but not of a permanent structural nature. Such a differentiation will be helpful and will make clear why loss of weight and many other things may occur in conditions of psychogenic origin. Often the general practitioner thinks that psychiatrists consider these bodily disturbances as being imaginary, which they do not. Though of psychogenic origin, their nature is physically organic. One thing that should be stressed in these cases is that what has happened to the patient often is that the emotional conflicts he has had (which he has either forgotten about or, if he remembers, he doesn't see in relationship to his present condition), and the fear, the anxiety, the general emotional upset were originally centered about some personal problems and later were transferred to the nervous, mental and bodily symptoms that he feels, and the fear therefore becomes firmly attached to his bodily, nervous and mental condition. It is well in handling such patients to point out to them in a definite way exactly what has happened. Dr. Wholey has stressed that in many of these cases there exist almost unsolvable personal and home situations, and no matter how cheerful and optimistic one may be in handling them, often they are really unsolvable. If the psychiatrist cannot acquire such a psychologic hold on the patient that his control is greater than the control of the member or members of the family under whose influence the patient may be, he is going to lose the fight.

Dr. Harry Stack Sullivan, Towson, Md.: I have made a research investigation of 260 patients suffering schizophrenic illnesses. In 70 per cent the presenting symptoms of illness were of a nature that brought the patient to the attention of a physician for something other than mental disorder. I have reached the conclusion that a considerable portion of preschizophrenic and actually psychotic youths might be saved from grave disorder and deterioration if the fact could be conveyed to the general practitioner and to the specialists in the fields that I have mentioned that this grave mental disorder frequently presents itself as fairly well disguised symptoms of various physical illnesses, treatment of which as such facilitates the destruction of the patient's self-confidence and the development of the grave disorder. Neurologists and psychiatrists have a great duty in educating the medical man to the importance of symptomatologic camouflage. This should be one of our principal activities as psychiatrists, on the one hand in influencing medical education, and, on the other, in dealing with all physicians who counsel with us and who are present as audience in joint meetings.

Dr. Cornelius C. Wholey, Pittsburgh: This sort of paper was presented in the hope that it might reach the general ranks of the profession. I shall not attempt to take up in detail the points that have been brought out. The discussion, however, has emphasized the fact that the understanding of these cases is not sufficiently disseminated among general practitioners. I am satisfied that this can be partly explained by the serious defect generally existing in medical education. Many medical schools do not emphasize the importance of mental factors in disease either sufficiently or early enough in the course. A discussion of the psychic factors in disease processes should be begun at the same time as discussion of disease processes from toxic and infectious and other causes. It is just as essential. It plays an equally important rôle. Unfortunately, it is often left to the end of the course and then deals principally with the less important advanced insanities, neglecting the more important psychoneuroses. This emphasis on the insanities misleads and discourages the student. It gives him the impression that all mental ills are hopeless, since he does not have the opportunity of dealing with the large group of curable cases, cases that arise from hysterical and psychogenic factors. Nor is he usually taught to appreciate the mental element frequently present in medical and surgical cases. It is regrettable that some members of medical staffs still look on the course in psychiatry as a thing that has to be tolerated, seeming to have little appreciation of the vital import of psychiatry in general medicine.

HYPOTHYROIDISM *

LOUIS M. WARFIELD, M.D.
MILWAUKEE

It has been only within recent years that the mild states of hypothyroidism have received any attention. The most recent textbooks on diseases of the thyroid gland still devote considerable space to cretinism and myxedema but say very little, or do not mention at all, the group of cases which present symptoms which appear to be associated with lessened thyroid secretion but which never reach the stage of myxedema. That there is such a group of cases is attested to by articles now appearing in the literature from widely separated parts of this country. Kocher in 1904 was the first to call attention to this group as a possibility, but only since the development of clinical metabolimetry has it been possible to recognize the condition with any degree of accuracy.

The thyroid gland, unlike the pancreas or the suprarenal glands, is not absolutely necessary to maintain life. "It is not essential to thermostasis; nor is it essential to metabolic acceleration. Epinephrine exerts its calorigenic action even in the thyroidless animal."[1] Yet it is one of the most important of the endocrine glands as it is admitted to be largely the activator of all the body cells. Von Noorden has said, "The thyroid acts on oxidation as a pair of bellows rejuvenates a fire." De Quervain[2] gives four principal functions to the thyroid gland based on clinical experience and physiologic experiments: (1) control and stimulation of tissue growth in general; (2) control and stimulation of the functional processes of tissues; (3) neutralization of toxic substances produced in the normal metabolism of the tissues, and (4) assistance in the defensive action of the organism against bacterial toxins.

The majority of authors will agree to these four functions although not all are yet experimentally proved. The difficulty in assigning to certain more or less abnormal body states an endocrine etiology is notoriously fraught with pitfalls. There has been too loose reasoning from hypothetic and insufficient premises. The fact that there are undoubted cases of hypofunction of the thyroid, pancreas, suprarenal and pituitary glands should not lead one to assign too much of human woe to the endocrine glands.

Enough surveys of school children and college men and women have been carried out within the last few years to leave no doubt that there are definite goiter districts in this country; that is to say, districts where from 70 to 85 per cent of the young girls and women and 20 to 30 per cent of the young boys and men have simple goiter. Among these districts the Great Lakes basin rates high. Not only do human beings but all the species of animals as well as many species of fish have goiter. The soil is poor in iodine, the drinking water has only a trace. The story of the prophylaxis of goiter by the use of iodized table salt is well known. Goiter, then, is endemic in this region. Years ago Hector Mackenzie said that in any endemic goiter district the population would eventually show signs of more or less thyroid failure. Here in the Great Lakes basin we are seeing the third and fourth generations

[2] De Quervain, Fritz: Goiter and Thyroid Diseases, New York, William Wood & Co., 1924, p. 184.

of the pioneers who came from the Eastern Seaboard, from Germany, Norway and Sweden, districts where goiter is rare. The settlers found a soil without iodine. The first generation obtained iodine from the mothers but owing to the lack of iodine in food and drink the mothers of each succeeding generation could not replenish their store in the thyroid gland and their daughters and granddaughters had less and less. Now we see not only endemic goiter but mild or moderately severe states of thyroid failure which have not yet reached the stage of cretinism as in some of the Swiss cantons. Now that the value of iodine in the prophylaxis of adolescent goiter is known and the obstetricians are giving pregnant women iodine, it is probable that future generations will not have the mild states of hypothyroidism seen today in such relatively large numbers.

I wish to emphasize that these cases are common and until rather recently have gone unrecognized, usually being put in the neurasthenic group or in the vague group known as a "run down condition."

All textbooks, including the recent monograph by Means and Richardson,[1] divide hypothyroidism into cretinism (sporadic or endemic), myxedema, and operative myxedema (Kocher's cachexia strumipriva). To this grouping of hypothyroid cases should be added masked or latent hypothyroidism, a condition in which certain symptoms are found, certain laboratory tests are found and the basal metabolic rate is low but in which there are none of the classic signs of myxedema.

ETIOLOGY

One must include in the etiologic factors the operation for subtotal thyroidectomy. Too frequently patients are operated on and are not observed subsequently. The operation is supposed to cure them and nothing to the contrary is said to them. Injuries to the thyroid gland in the course of infectious diseases have been considered a cause. Kocher called attention to mild states of hypothyroidism following severe general infections, typhoid, influenza, dysentery, furunculosis. De Quervain[2] states that "the slighter forms of hypothyroidism occur in patients whose glands have been damaged by an inflammatory affection or by endemic goiter." The latter cause would appear to be the most important one in a goiter region. Tuberculosis and syphilis are not causative factors. In women the period of onset of menstruation and again the cessation of menstruation seem important factors in etiology.

Ninety-five per cent of my patients were born in states bordering on the Great Lakes and had lived most of their lives in this region. Five per cent were born abroad or in states east of the Blue Ridge Mountains but had lived in this region since infancy or early childhood. Although this does not prove the influence of locality, it is interesting. Undoubtedly thousands of persons with slight degrees of thyroid failure are daily carrying on their work and pass as normal. It is not the degree of thyroid failure alone measured by the basal metabolic rate which bring on symptoms. There evidently is some unknown constitutional factor which is also operative.

SYMPTOMATOLOGY

One might say at the outset that there is no definite group of symptoms which characterizes the mild hypothyroidism cases. The neurasthenic syndrome comes nearest to it but that only shows how bizarre is the symptomatology. These people are not really ill; they are below par. They do not feel as well as they know they should. Many are teachers or executives who hold responsible positions, who are active and energetic but who feel conscious that they have to drive themselves to their tasks, and they tire out easily. A rest often makes them feel quite well again, but as soon as they are back at work the same weariness comes over them, especially at the end of the day's work. It seems as if there were no reserve on which the patient can call. His activities use up his store of energy and leave him nothing on which he can fall back. This sense of fatigue is one of the most constant and characteristic symptoms.

Constipation, a sluggishness of peristalsis, is the next most common symptom in my series. Deusch[3] has shown that thyroid extract acts on strips of intestinal muscle to improve the tonus and to lower the threshold of stimulus response. The constipation is a lack of tone, not any actual pathologic lesion. This symptom has been noted by all authors. Brown[4] has called particular attention to it in women over 40 who have a lowered basal rate.

Headache is common. At times it is of a distinctly migrainous character. Lawrence and Rowe[5] have reported such cases in which the diagnosis of migraine had been made over a period of several years. None of my cases were of this type but fifteen patients gave headache as the most important symptom, the pain usually being on top and moving toward the occiput.

Rheumatic aches and pains were complained of in a few cases. These were cases now prone to be labeled "focal infection."

Vague abdominal pains often diagnosed as chronic appendicitis are also complained of as the prominent symptom. This is important to bear in mind. Too many people are rushed into hospitals and have had unoffending appendixes removed. Needless to say, they are often worse after the operation. The pain is still there and confidence in doctors has been shaken.

Menstrual disturbances in women are not as frequent as one might think. There were five of my patients who were irregular, six who had scanty flow and six who had increased flow. Salzman,[6] in the period before clinical metabolimetry, reported cases of uterine hemorrhage in which a normal condition was restored by the feeding of thyroid extract.

The weight is exceedingly interesting. All descriptions of hypothyroidism (which is always a synonym for true myxedema) in textbooks call attention to gain in weight. This conception needs revision. Lawrence[7] has already specifically called attention to the underweight (not starved) hypothyroid. I can confirm his observation. In this series of 88 patients, 22 definitely complained of or were found to be underweight, 21 had gained in weight, and 45 did not vary more than any normal person would. The overweight patients complain that however little they eat they gain, the underweight patients complain that although they stuff themselves they cannot increase their weight.

Beck[8] reports cases of nycturia, pollakiuria, dysuria, oliguria and incontinence due to thyroid failure. In the urine were pus and squamous cells. Endothelial cells were shed prematurely. He considers that the lack of thyroid secretion is responsible for the urinary disturbances and for the shedding of the epithelium of the kidney tract.

Lee[9] has found cases of vasomotor rhinitis of months' duration in young adults in whom nothing abnormal was found but a low basal metabolic rate. Complete relief was obtained by the feeding of thyroid extract. This is a small group but is actually existent.

The classic symptoms of the textbooks, such as thick skin, dry hair, dry skin, susceptibility to cold, scanty eyebrows and pads of fat above the clavicles, are conspicuous by their absence. Occasionally, if asked a direct question, some patients will admit susceptibility to cold.

Physical Signs.—There are no physical signs characteristic of this group of mild hypothyroid cases.

No particular size or weight or body figure is found. The thyroid gland may or may not be visible or palpable.

The pulse rate and blood pressure vary as they do in any group of people. Occasionally one finds a rapid rate, from 90 to 110. This is noted in the literature by Higgins,[10] Lawrence[11] and others.

The lowest blood pressure among my cases was 90 systolic and 70 diastolic in a woman, aged 40, whose pulse rate was 64, whose basal metabolic rate was minus 30 per cent and whose lymphocytes were 20 per cent. The highest blood pressure was 190 systolic and 94 diastolic, the pulse rate 100, in a woman, aged 61, with a basal metabolic rate of minus 16 per cent.

The blood does not show constant changes. Kocher's original differential point, a relative lymphocytosis, is not invariably present but more than 30 per cent of large and small lymphocytes were found in one half of my cases. Occasionally chlorotic types of anemia,[12] and even pernicious-like[13] blood pictures, have been reported. Simple anemia is not infrequent.

The basal metabolism rates[14] in the series ranged from minus 11 to minus 32 per cent. Criticism might be directed against considering as hypothyroidism a figure so close to the so-called normal as minus 11 per cent. While the standard usually given for normal is ± 10 per cent, the ease with which an increased basal rate may be obtained, and the practical impossibility under test conditions of decreasing the rate, makes a consistent minus 10 per cent with symptoms significant for the diagnosis of hypothyroidism.

I do not wish to leave the impression that every patient who is found in the course of an examination to have a lowered basal metabolic rate is suffering from thyroid or any other endocrine gland failure. Many perfectly well persons are found to have a rate of minus 10 or lower. These may be mild posterior pituitary failures (Cushing[15] believes that there are many such persons in the population), mild ovarian failures or mild suprarenal failures or perfectly normal persons. Slightly lowered basal metabolic rates may be without any significance. The point to be stressed is that in a patient with certain indefinite symptoms, of which easy fatigability is the chief one, with no other cause after careful search and with a lowered basal metabolic rate, thyroid failure is to be seriously considered. If the problem is approached from this angle, a differential diagnosis being made in every case, then by therapy and careful observation it can be determined whether the diagnosis is correct or not.

Usually patients with hypothyroidism have had symptoms for many months, even years. It is not always easy to fix the time of the onset of symptoms. In a series of cases which Lawrence[7] reported, the average length of time of symptoms was eight years. The longest interval in my series was twelve years, the onset dating from an attack of measles followed by scarlet fever.

Blood Sugar.—One finds in the literature the statement that there is hypoglycemia in hypothyroidism. Janney and Isaacson[16] say that all hypofunction of the endocrine glands, of which the thyroid is an example, are accompanied by hypoglycemia. Geyelin[17] has reported very low blood sugar values in two cases of myxedema, 53 and 68 mg. per hundred cubic centimeters. Janney and Isaacson's cretin showed 65 and 70 mg. They also showed that within two weeks after thyroidectomy on dogs there was hypoglycemia and a prolonged sugar curve (increased tolerance). However, cases of untreated myxedema are reported in which there was mild glycosuria.

Lawrence and Rowe,[5] in their studies of cases of hypothyroidism (not myxedema), say that there is a slight hypoglycemic tendency in thyroid failure. If 110 mg. per hundred cubic centimeters is accepted as the upper level of venous blood sugar, then about one half of my cases in which blood sugar estimations were done show higher values. No case showed hypoglycemia. Although the number of my cases is not great, still the figures apparently show that in the type of thyroid failure dealt with in this paper hypoglycemia is not present.

DIFFERENTIAL DIAGNOSIS

It is often difficult but highly important to make an accurate diagnosis. It does not seem that it is necessary to go to the extreme in laboratory examinations that Lawrence and Rowe have done. It is doubtful whether one could persuade the average private patient to subject himself to such a variety of tests, especially when he found out what the cost probably would be. Physicians who are subsidized in large endowed clinics can carry on extensive and expensive studies on a limited number of patients. The information obtained is valuable and serves to further knowledge; but it is not practical to carry on elaborate investigations in the study of cases coming to private physicians in all parts of the land.

The most important single test in the differentiation of the hypothyroid group from other endocrine gland failures is the determination of the basal metabolic rate. Much has been said of the difficulties and fallacies of this test, to all of which I agree. *The fact remains, however, that no diagnosis of hypothyroidism can be made unless there is demonstrated a lowered basal metabolic rate.*

Lowered basal metabolic rates are found in pituitary failure, in ovarian failure and in suprarenal gland failure. Benedict says that inadequate protein intake will lower the basal rate independently of the remainder of the diet.

Patients with pituitary failure have been shown to have a rather characteristic distribution of fat over the body. This is found on physical examination. Ovarian failure is so intimately associated with both pituitary and thyroid failure that it should cause no great difficulty in diagnosis. Careful thyroid feeding under rigid observation is of help in differentiation if doubt exists in the mind of the physician.

The important and most difficult differentiation is that between hypothyroidism and hyposuprarenalism. The metabolic rate in both is low, but the latter is never as low as the extreme figure obtained in the former.

Koehler's[18] average basal metabolic rate for 288 cases of hypothyroidism was — 26 per cent, for 63 cases of hyposuprarenalism — 17 per cent. He says that because of autonomic instability it was difficult to obtain accurate rates in the hyposuprarenal cases. He publishes charts showing the regular respiratory excursions of the hypothyroid contrasted with the very irregular excursions of the hyposuprarenal case. In a review of my cases, with this point in mind, I could not confirm his observations. Possibly there were no instances of hyposuprarenalism among my cases. He thinks that hyposuprarenalism may exist with a normal or even slightly elevated basal metabolic rate. I feel that there can be no hypothyroidism without a lowered basal rate.

In my experience the most common disease that has to be differentiated from mild hypothyroidism is occult tuberculosis. Unless there is malnutrition, the normal basal metabolic rate in tuberculosis and the presence of a very positive intradermal old tuberculin test are helpful differential points. One cannot make a diagnosis of hypothyroidism unless there is a lowered basal metabolic rate.

A sense of ill being is so common in the onset of many chronic diseases that only careful analysis of all the data obtained will prevent errors in diagnosis.

TREATMENT

If the diagnosis is correct, the treatment is specific. Either thyroid extract or dessicated gland can be used. There seems to be no valid reason for giving thyroxin, which has to be administered hypodermically or intravenously when administration of the gland substance by mouth will produce the desired result. The dose varies to some extent with the depression of the metabolic rate. Large doses are to be avoided. It is better to begin with a dose that will certainly not do harm, from 2 to 4 grains (0.13 to 0.26 Gm.) daily of thyroid extract, and then check the basal rate in from ten days to two weeks. For each individual there is an optimal dose which must be found by experiment.

It is neither necessary nor desirable to bring the metabolic rate to normal. I have patients who have been taking from 3 to 5 grains (0.2 to 0.3 Gm.) of thyroid extract daily for more than two years. In none of these is the metabolic rate up to minus 10. It is not the figure of the basal metabolic rate but the well being of the patient which is the criterion for dosage.

Occasionally it is found that, after the administration of small doses of thyroid extract for from ten days to two weeks, the next basal metabolic rate is appreciably lower than the initial rate. Squier[19] has noted this. Swaim,[20] working with arthritic patients, has called attention to this phenomenon and explains it by assuming that the thyroid extract produces lessened tension in an organism which lacks the normal amount of thyroid hormone. It is, of course, possible that the second estimation finds the patient accustomed to the machine and the operator and his relaxation is more complete. Nevertheless, in what appears to be perfect duplicate estimations on first and subsequent tests, the second may be from 10 to 12 per cent lower than the first.

SUMMARY

Mild to severe grades of hypothyroidism (not myxedema) are common among persons living in a goiter region such as the Great Lakes basin.

All classes of people are affected; a considerable proportion are professional men and women.

Both underweight and overweight as well as normal weight are found among the patients.

The most important single symptom is an undue sense of fatigue, a physical exhaustion which often leads to a neurasthenic state.

Other frequent symptoms are constipation, susceptibility to mild infections such as coryza, various aches and pains, and, in women, scanty or profuse menstruation.

General abdominal soreness, especially along the colon and in the right iliac fossa, is frequent.

Diagnosis cannot be made without evidence of a low basal metabolic rate, as there are no pathognomonic symptoms or signs for the mild hypothyroid state.

Differential diagnosis must be made from other endocrine gland failures, especialy suprarenal, posterior pituitary and ovary: from such chronic diseases as (1) occult or incipient tuberculosis, (2) diabetes, (3) chronic nephritis, (4) pernicious anemia and other blood diseases.

Rheumatic aches and pains and headaches of a migraine type may be due to thyroid failure.

Thyroid extract can only normalize the nutritional needs of the body and should never be administered to reduce weight in individuals with normal thyroid function.

193 Prospect Avenue.

ABSTRACT OF DISCUSSION

Dr. T. L. Squier, Milwaukee: The subject Dr. Warfield has presented is of great interest, especially in this region. The view that in the Great Lakes basin, where goiter is prevalent, mild grades of thyroid insufficiency should be expected is fascinating and plausible. The number of lowered metabolism cases seen in the group usually classed as neurasthenic who complain of chronic fatigue is striking and the improvement in general well being of many in this group under thyroid therapy is most gratifying. Lowered metabolism can be caused by many factors other than hypothyroidism and even the therapeutic test does not establish a diagnosis. However, when improvement occurs one must wonder whether it results from actually supplying a thyroid lack, from pure psychotherapy, or from other unknown factors.

Almost without exception, those who have followed patients of the type described by Dr. Warfield have been impressed by the marked benefit seen after thyroid therapy. It is to be hoped that sometime it will be possible to make a differential diagnosis between hypometabolism and hypothyroidism. In the meantime the empiric use of thyroid extract, controlled by frequent metabolism tests, in those patients with a lowered rate who have symptoms, seems logical and justified.

Dr. C. N. Hensel, St. Paul: Since I have been recognizing and treating for the past three years such patients as Dr. Warfield has just described, I can heartily endorse what he has said. The profession is still imbued with the idea that underfunctioning of the thyroid gland is characterized by a myxedematous infiltration of the skin, increased body weight and mental sluggishness. In the absence of this syndrome, physicians do not even think of underfunctioning of the thyroid gland as a cause of fatigability and a feeling of incapacity either mental or physical. It is surprising how few patients with an underfunctioning thyroid gland are overweight, have a rough dry skin, or falling hair. Certainly half of my hypothyroid patients are of normal weight and possibly one fourth are even below weight, so that one cannot go on the objective manifestations but must accept the patient's subjective sensations, the first and most constant complaint being fatigability. Unlike the neurasthenic who hides behind his symptoms, the hypothyroid patient is annoyed with his inadequacy. One is surprised to find in this hypothyroid group plenty of active alert mental workers—executives, writers, school teachers, physicians, the lean type, the active driving type, sales managers, those who are trying to put energy into other people. Since I began to recognize this syndrome as a clinical entity and check my impressions by basal metabolimetry and institute treatment with desiccated thyroid gland, I have been amazed to see how many people have been helped back to a state of comfortable well being. I have even recalled my office patients whom I was unable to help four or five years ago, checked their basal metabolic rates, found them low, given them thyroid extract and seen them become happier, more vigorous and more efficient.

[18] Koehler, A. E.: Differential Diagnosis Between Hypothyroidism and Hyposuprarenalism, J. A. M. A. **91**: 1457 (Nov. 10) 1928.

[19] Squier: Personal communication to the author.

[20] Swaim, L. T.: Chronic Arthritis: Further Metabolism Studies, J. A. M. A. **93**: 259 (July 27) 1929.

Dr. Leopold Lichtwitz, Altona, Germany: Hypothyroidism may sometimes be an independent disease. In other cases, of course, hypothyroidism is a part of other disturbances. Hypothyroidism, especially, may be the result of starvation. It is also known that it is a part of disturbances of the pituitary body, especially of atrophy or destruction of the anterior lobe. In these cases the basal metabolism is also low (— 30 per cent). From the clinical point of view, it is important to note that there are cases of hypothyroidism in which severe anemia is a symptom. I remember, for instance, the case of a woman, aged 30, who suffered from a severe anemia for which she had been treated without result for a long time. One week after beginning the administration of thyroidin, the anemia disappeared and the blood pressure was normal. The retention of water in the hypothyroid condition is remarkable. This water is removable from the body only by means of thyroidin. As Boothby found (and I have been able to confirm his work) the output of this fluid is in close relationship to the output of nitrogen. This means that the fluid retained in hypothyroidism consists of a certain amount of protein. In addition to the state of general hypothyroidism, the occurrence of symptoms of partial hypothyroidism, which are of especial interest in the condition of general hyperthyroidism, must also be taken into consideration. In some cases of exophthalmic goiter, evidences of hypothyroidism make their appearance in later years. It is rather difficult to understand this combination, but it is perhaps possible to do so if it is considered that the function of hormones generally consists of four parts: 1. The material for the formation of hormones. (In the case of thyroxine this material is thyrosine and *p*-oxphenylalanine.) 2. The formation of the hormone from the mother substance in the cells of the endocrine glands. 3. The excretion of the hormone from the cells. 4. (I believe this is a very important consideration.) The ability of every tissue, organ, and cell to take the hormone from the blood. I suggest that in some cases of disease due to hormone deficiency the fault may lie in the inability of the tissue to fix the hormone. If this fault concerns parts of the tissues only (the skin, for instance) a partial hypothyroidism is possible, even though general hyperthyroidism is present.

Dr. Louis M. Warfield, Milwaukee: One important point to remember, is that thyroid extract is a potent substance and those who give thyroid extract with the expectation of reducing weight should bear in mind that weight reduction, while it may occur, is often accompanied by symptoms so serious that the weight reduction itself is due to the toxicity and not to the beneficial effect of the thyroid extract. Thyroid extract can only normalize the nutritional needs of the body and should never be administered to reduce weight in individuals with normal thyroid functions.

INTRADERMAL, SCRATCH, INDIRECT AND CONTACT TESTS IN DERMATOLOGY

A COMPARATIVE STUDY *

MAXIMILIAN A. RAMIREZ, M.D.

AND

JOSEPH JORDAN ELLER, M.D.

NEW YORK

This presentation is a report of a comparative study of four types of sensitization tests on a series of 500 patients with dermatoses in whom the etiology was suspected to be of allergic origin. From 200 to 400 tests were done on each patient.

Table 1.—*Total Number of Cases Tested, Divided into Groups*

Clinical Diagnosis	Number of Cases
Urticaria	126
Herpes labialis (recurrent)	8
Angioneurotic edema	18
Neurodermatitis (pruritus with lichenification)	77
Dermatitis medicamentosa	46
Potassium iodide (intravenous)	14
Potassium iodide (mouth)	8
Phenolphthalein	2
Dover's powder (ipecac)	1
Sodium bromide	11
Phenobarbital	6
Salicylic acid	4
Endogenous eczematoid dermatitis	114
Contact dermatitis	105
Zinc oxide	1
Iodine	2
Creosote	1
Glycerin	1
Ursol (fur dye)	2
Barbasol	2
Newspaper:	
Brown section	2
Daily paper	2
Contact dermatitis—Cont.	
Quinine	4
Procaine	4
Ephedrine	4
Fox fur (undyed)	2
Beaver (undyed)	1
Glue	2
Poison ivy	16
Primrose	1
Dandelion	1
Pollen:	
Ragweed	4
Timothy	1
Pyrethrum	8
Kapok	2
Silk	18
Rayon	1
Wool	4
Cat hair	1
Dog hair	1
Horse hair	4
Human hair	1
Cotton	1
Flax (linen)	1
Orris root	9
Rabbit hair	1
Photodermatitis, sunlight	4
Thermodermatitis	2
Cold air	1
Heat	1

The dermatologist of today is making an earnest effort to treat the various dermatoses from the standpoint of their specific etiology. We realize that many dermatologists are discouraged at the lack of aid which they have obtained in the past from sensitization tests.

Table 2.—*Cases Giving Positive Skin Reactions by One or More Methods*

Total Number Tested	Clinical Diagnosis	Number of Cases	Percentage
126	Urticaria	96	76.2
8	Herpes labialis	6	75.0
18	[illegible]	12	66.7
77	[illegible]	52	67.5
46	[illegible]	2	4.3
114	[illegible]	98	85.9
105	[illegible]	92	87.6
4	[illegible]	4	100.0
2	[illegible]	2	100.0

As a result of the observations herein presented, we are convinced that one may be more optimistic in this regard.

It is most important that sensitization tests be interpreted by one who is experienced. A sufficient number of tests must be done to include all sources of exposure in each case. Tests should be repeated several times by different methods if indefinite or suspicious reactions are obtained to a suspected substance. In interpreting reactions one should realize that patients at times are in a so-called refractory state and will not react even to substances to which they are highly sensitive. Also during a state of skin hyperirritability a wheal and erythema may occur at every tested area, including the controls. This state of skin hyperirritability may be fairly localized or generalized. It may be temporary or persistent, in which case it is practically impossible to interpret skin reactions accurately. In these cases the indirect method of testing is of particular value and is the method of choice. Thorough catharsis and rest in bed on a limited diet will often lessen the irritability of the skin.

* Read before the Section on Dermatology and Syphilology at the Eighty-First Annual Session of the American Medical Association, Detroit, June 27, 1930.

TABLE 3.—*Number of Cases Proved to be Caused by Substance Giving Positive Skin Reaction*

Total Number Tested	Clinical Diagnosis	Reacting to Tests, Number	Proved as Due to Substance Giving Positive Reaction: Number	Per Cent	Substance
126	Urticaria	96	14	14.5	
8	Herpes labialis	6	1	16.7	Chocolate
18	Angioneurotic edema	12	4	33.3	Fish, celery, brazil nut
77	Neurodermatitis	52	3	5.7	Wheat, barley, egg
46	Dermatitis medicamentosa	2	2	100.0	Phenolphthalein Dover's powder
114	Endogenous eczematoid dermatitis	98	9	9.0	
105	Contact dermatitis	92	81	88.0	
4	Photodermatitis	4	4	100.0	
2	Thermodermatitis	2	2	100.0	

TABLE 4.—*Cases Failing to Give Positive Skin Reactions to Substances Proved to be the Cause of the Dermatosis* *

Total Number Tested	Clinical Diagnosis	Cases, Number	Due to Specific Substance, Number	Per Cent	Substance
126	Urticaria	30	0	0.0	
8	Herpes labialis	2	0	0.0	
18	Angioneurotic edema	6	2	33.3	Whisky; mushroom
77	Neurodermatitis	25	0	0.0	
46	Dermatitis medicamentosa	44	44	100.0	
114	Endogenous eczematoid dermatitis	16	10	62.5	Banana, 1; orange, 2; excess fats, 4; excess carbohydrates, 3
105	Contact dermatitis	13	3	23.0	Newspaper, 1; barbasol, 1; quinine, 1
4	Photodermatitis				
2	Thermodermatitis				

* Proof is based on disappearance of symptoms by withdrawal of offending substance and recurrence on renewed exposure.

The accompanying tables show in tabulated form the results of sensitization tests in the present series of cases.

The following are case histories taken from our series and presented because of their unusual interest:

REPORT OF CASES

CASE 1.—A boy, aged 11, had had asthma and persistent dermatitis for the past two years, with occasional periods of freedom and with definite exacerbations every week-end. The boy made a practice of visiting his uncle on a farm every week-end throughout the year and slept in the same bed with him. After protracted testing and investigation, it was shown that the asthma and dermatitis were both due to a specific hypersensitiveness to human hair (uncle's hair). Tests with extracts of hair from other members of the family were negative. At first it was thought that possibly something in the bed or room on the farm was responsible rather than the hair. The uncle was prevailed on to spend one week-end in New York and sleep in the same bed with the patient, who had always been free from asthma in New York. The child had a severe attack of asthma and an exacerbation of the dermatitis. The following week-end the boy was instructed to go to the farm, and to sleep in a room, not with his uncle. The result was absolute freedom from symptoms.

TABLE 5.—*Results of Different Methods of Testing in Groups Giving Positive Reactions*

CASE 2.—A Negro man, aged 54, had had almost daily attacks of giant urticaria and angioneurotic edema involving various parts of the body during the past two years. Repeated tests and treatments were of no avail. The removal of a definitely abscessed tooth caused an immediate and permanent disappearance of all symptoms. A culture taken from the socket and from the root of the tooth showed a pure growth of *Streptococcus hemolyticus* and a testing suspension prepared from this organism gave a very strongly positive skin reaction by the intradermal method. Passive transfer tests were negative.

Case 3.—A boy, aged 11, was sensitized to silk. The avoidance of contact with silk resulted in an almost complete disappearance of the skin lesion and an exacerbation on renewed contact. This case is presented because of the typical clinical appearance and history of neurodermatitis.

Case 4.—A woman, aged 32, for the past five years had had a pruritic eruption on the face, neck and hands. These symptoms began during the last week of August or the early part of September and lasted until the middle of October. In 1928, the eruption persisted until December. There was no history of asthma, hay-fever, urticaria or migraine. The family history was negative. Skin tests were positive to giant and short ragweed by the scratch, the intradermal and the patch method of testing. Passive transfer tests were also positive. A series of injections with mixed ragweed, started in March, 1929, and continued until October, 1929, proved successful. The patient had no discomfort throughout the ragweed season. Without outlining in detail the case histories of other ragweed dermatitis cases, we wish to point out that two of our patients who also had symptoms of hay-fever and reacted positively to scratch and intradermal tests did not react by the patch or contact method of testing. One gave a positive passive transfer and the other did not. Both of these patients were free from symptoms following immunization.

Case 5.—A chauffeur, aged 26, had had hay-fever in the spring and fall for the past eight or ten years. He had had a persistent pruritic eruption on the face and hands for the past two years. It started in August, 1927, and with brief periods of improvement had persisted ever since. Skin tests were strongly positive to timothy, June grass, ragweed, and pyrethrum by scratch and intradermal tests. A positive patch test was obtained only to pyrethrum. Passive transfer tests were negative. Cases of pyrethrum dermatitis are well known to dermatologists. The reason for reporting this case is that it was definitely proved that the source of contact was "Flit," which was used by the patient to spray the inside of the car several times a week. Another point of interest is that a positive patch test was obtained in this case to pyrethrum, which was eventually shown to be the important etiologic factor and a negative patch test to the other pollens which, though responsible for the associated hay-fever, were not related to the dermatitis.

2	Thermodermatitis	2	..	....	..	....	..	....	0	0.0

Case 6.—A girl, aged 17, had a dermatitis on the neck, chest, arms, legs and abdomen of two years' duration. There was no history of hay-fever, asthma or urticaria, and the family history was negative for these conditions. Skin tests were negative except to an extract of rayon, which gave a strongly positive reaction by the scratch, intradermal and patch methods but a negative passive transfer. Rayon is made from a vegetable fiber or from wood pulp. It is impossible to determine the exact source of the rayon used in the manufacture of a given piece of material, as many varieties are usually used in making up a single piece of cloth. This case was absolutely negative to real silk and was cured on removal of contact with rayon.

Case 7.—A woman, aged 42, had had asthma and urticaria for the past three months. The symptoms appeared only after retiring in her own room, where she had lived for many years. It was found that change of environment immediately relieved the asthma as well as the urticaria and a return to her own room caused a return to the symptoms. After much investigation a definite sensitization to a green penicillium was established. A culture of this fungus was obtained by exposing Sabouraud plates in her room. Positive skin tests were obtained with a saline extract by the scratch and intradermal methods of testing and a positive passive transfer of reacting antibodies demonstrated. The patient is still under treatment with injections of an extract of the mold to which she is specifically sensitive. She also has changed her residence and has been free from all symptoms.

Case 8.—A woman, aged 36, had a dermatitis due to sensitization to the rotogravure section of a Sunday newspaper and also to the daily newspaper. We have had several such cases associated with perennial sneezing and one case with mild paroxysms of dyspnea. This patient had a dermatitis of both hands of two years' duration. A positive skin reaction was obtained by the scratch, intradermal and patch methods to both the rotogravure and the ordinary daily newspaper. Tests with pure para red, with black printers' ink, with printing paper before it went to press, and with extracts of wood pulp from willow, birch and spruce (which are the trees ordinarily used in making paper) were all negative. Repeated tests with the printed newspaper itself were positive. Absolute avoidance of contact resulted in a complete disappearance of the dermatitis in a few weeks and a recurrence after a week of renewed exposure.

Case 9.—A man, aged 52, had had a dermatitis in the region of the upper lip and sides of the nostrils for the past two months, and also asthma for twelve years. By skin tests as well as by removal of the offending substance and again by renewed exposures, it was proved that the dermatitis was due to sensitization to ephedrine used in a nasal spray. It is interesting to note that the same ephedrine nasal spray had been used daily by the patient for about two years without skin symptoms, and that only within the past two months did the dermatitis appear.

Case 10.—A woman, aged 22, had had a recurrent dermatitis of both hands for the past three years. Extracts prepared from dust obtained from old books in her father's library, which she handled and arranged almost every day, produced a positive skin reaction. Tests to leather and paper were negative. There was a positive reaction to glue and to several fish extracts. Ingestion of a large amount of fish caused an attack of urticaria and severe headache.

Case 11.—A dentist, aged 32, had had a recurrent dermatitis of both hands and face for the past eight months. There was no history of asthma or hay-fever but occasional attacks of generalized urticaria. Tests demonstrated the cause of the dermatitis to be ethyl alcohol. A reaction was obtained by the intradermal and the patch methods, but the tests were negative with the scratch and the indirect methods. Avoidance of contact resulted in a disappearance of the persistent eruption, and renewed exposure caused a recurrence.

Case 12.—A man, aged 39, had had recurrent attacks of urticaria on the hands and face for the past two years. Wheals appeared only on exposure to cold air. There was no history of asthma or hay-fever. The family history was negative. Exposure to cold air produced an urticarial eruption within one minute. Applications of ice and other skin tests were negative.

SUMMARY AND CONCLUSIONS

Sensitization tests are a distinct aid in the diagnosis of dermatoses if carefully performed and interpreted.

A thorough and complete immunologic survey must be done in each individual patient and tests repeated when necessary.

The patch or contact method of testing is superior to other methods in determining susceptibility to external irritants, particularly those of nonprotein structure.

The intradermal method of testing is more sensitive than the scratch. It is more apt to produce false local reactions as well as alarming systemic reactions in the highly sensitive. It is preferable to use the scratch method first and check up with the intradermal.

The indirect method of testing, using the principle of local passive transfer as demonstrated by Prausnitz and Kustner, has its field of distinct usefulness. This is particularly true in very young children in whom it is difficult to do a large series of tests. It is also useful in patients with a persistent hyperirritability of the skin and when the dermatosis covers such a large area that direct testing would be impracticable. The indirect method of testing has its limitations. One cannot always demonstrate the presence of specific reagins even in cases proved to be specifically sensitive. It is not especially useful in cases hypersensitive to external excitants of nonprotein nature.

ABSTRACT OF DISCUSSION

Dr. F. J. Eichenlaub, Washington, D. C.: The authors present a large number of figures relative to the relation of allergy to various dermatoses. Before considering their figures in detail I would emphasize the fact that their concept of the subject is a broad one. Broadening one's conception will strengthen one's knowledge. They include everything causing the phenomena recorded. In table 4 are recorded four cases of endogenous eczematoid dermatitis due to an excess of fats and three to an excess of carbohydrates. I believe that most dermatologists would regard these cases as eczema of metabolic origin, rather than allergic in the commonly accepted sense. Some of the cases recorded could in actual practice be correctly ferreted out from an intelligent history and from the appearance of the lesions. This is particularly true in many cases of dermatitis venenata and urticaria. Thus, the various tests are often unnecessary in ordinary practice, although invaluable for scientific analysis in such papers as this. It is perhaps fortunate that such is the case. In this study I note, for instance, that in table 3 tests were made in 500 cases. Of these, 362 gave positive reactions but only 120 cases proved to be attributable to the substances to which they reacted. In table 4 I note that 136 failed to give positive reactions to any of the tests, although in 57 of these the cause was discovered by other methods. In spite of these seemingly discouraging figures, I believe the present study is a cause for distinctly more optimism in this field. In my own work I have found the scratch and intradermal methods of testing sensitization discouraging. With the addition of contact testing and passive transfer, however, many puzzling cases may be solved which now resist efforts at treatment. With the data given here and in similar papers I think the present position of sensitization testing for ordinary practice can be summarized as follows: 1. In a majority of cases the causative factor can be elicited by the combination of intelligent history taking and clinical experience. 2. In the smaller number of cases that resist ordinary methods the use of any or all of the methods outlined in this paper should be vigorously pursued in an effort to detect the etiology. 3. Possible constitutional factors in many of the cases, particularly in neuroses, should not be overlooked.

Dr. Harry M. Hedge, Chicago: I wish to ask for a little more information regarding three cases I observed during the last year. The patients were sent to the sensitization department to determine their activity to silk. They had a lichenified eruption and all cases resembled one another. There was marked itching and lichenification and it was determined that each of the patients was sensitive to silk. I took sections of their own dresses and sections from a silk smock belonging to the secretary in the social service department, and sections of my tie, which was silk, and fastened them on their arms, one wet and one dry, and none of these individuals responded to the scratch test. They claimed to be very sensitive and to be troubled even when riding on a street car or bus next to a silk dress, and to be unable to wear any silk, including hose. I notice that these investigators have found a large percentage of positives, and I wish to know why these patients did not show any reaction to the scratch test. Their idea was that when they were away from silk they had no difficulty. I should like to know whether there was anything in the mental element in these cases.

Dr. Walter J. Highman, New York: When the Wassermann reaction burst on the public, the words Wassermann and syphilis became synonymous. Repeatedly, with scientific methods of considering diseases, a patient will be thought not to have eczema if he does not have a positive scratch test. This is not due to the investigators. The tests indicate the way in which many eczemas may be produced. It is not necessarily implied that since these tests exist everything about the disease is known, or that these tests are optimal for every case. The procedure is merely one way of studying such cases. The fact that the tests do not always work with subjects in whom they should, or that they do work in subjects in whom they should not, indicates only the human limitations involved. Ultimately I hope these problems will be worked out, but dermatologists should not get into the state of mind that, because they have another method of approaching the problem, the problem will necessarily be solved by the application of only this method. Unfortunately, syphilis has survived the misinterpretation of the significance of the Wassermann reaction. The patch test is not eczema.

Dr. Fred Wise, New York: Many cases of neurodermatitis are seen in New York, and tests have been disappointing. In view of the fact the neurodermatitis often occurs in association with asthma and hay-fever, one would expect that, in this disorder, positive skin tests would be more likely to be obtained. As a matter of fact, I have been unable, both in the office and at the clinic, to obtain positive tests in neurodermatitis. Many still consider neurodermatitis to be a form of eczema; but the fact that the patch test in the hands of Drs. Ramirez and Eller is usually negative, and the scratch test often positive, indicates that the two diseases are inherently different types of skin disease and it would be gratifying to me if the men who see a large number of these cases in different cities would make these tests that have been described and report their results at future meetings, especially in neurodermatitis.

Dr. Marion B. Sulzberger, New York: The discussion has centered about the value of skin tests and the comparative value of the different types of tests. There is only one way to ascertain this, and that is by statistics. They all differ, depending on how they are carried out, and there is a great variation in the results obtained by different men. This is only natural. A man must be a detective to find the cause of an obscure dermatitis. Sometimes very small things will give a clue, and it is really more detective work than other branches of medicine, although all diagnoses seem to me a higher form of detective work. I agree absolutely with what Dr. Wise said regarding neurodermatitis. I sometimes think that a neurodermite belongs more to the urticarial than to the eczematous type of eruption. Frequently papular urticarial elements are seen which are reactions of the very superficial regions of the cutis. I believe that many cases of neurodermite may be intermediate between urticaria and true eczema in their pathogenesis. I think, in this connection, that something more can be worked out about neurodermite, and it would be interesting to have statistics of the frequency of occurrence of urticaria and neurodermite in the same patients.

Dr. M. W. Rubenstein, Pittsburgh: Professor Gans pointed out that neurodermatitis has its origin in the urticarial type of lesions. This contention is evidently borne out by the remarks of the authors and by the scratch test, that neurodermatitis does not belong to the vesicular or eczematoid type of reactions but does belong to the urticarial group.

Dr. Maximilian A. Ramirez, New York: There is great danger of becoming overenthusiastic about any method that is in popular favor. This is true not only in dermatology but in many other things. The term "allergy" is so loosely employed now that a stage has been reached in which no one knows what allergy is or what is being talked about.

RELATION OF INFECTION OF THE EAR AND INFECTION OF INTESTINAL TRACT IN INFANTS

RESULTS OF FIVE YEARS' STUDY *

D. E. S. WISHART, M.B.
Assistant Surgeon, Department of Laryngology, Hospital for Sick Children; Junior Demonstrator, Department of Otolaryngology, University of Toronto Faculty of Medicine
TORONTO

This paper is an attempt to answer the question: Is infection of the mastoid the cause of acute intestinal intoxication in infants?

During the past five years this question has been intensively studied by pediatricians and otologists in Canada and the United States. The literature has been ably reviewed by G. M. Coates.[1] The students of this problem are at present roughly divided into two widely divergent camps: those who believe that infection of the mastoid is the cause of acute intestinal intoxication in infants and those who believe that it is not. Physicians and surgeons of eminence are to be found in each camp, but the majority of their papers support, to some extent, the idea that infection of the mastoid antrum may be the cause of this mysterious disease.

THE DISEASE

An intense form of gastro-intestinal disease affecting infants under 2 years of age, occurring apparently in epidemics, and exceedingly fatal in its effects, is known under several titles, of which acute intestinal intoxication, acute infectious intoxication and cholera infantum are the most frequently used. The disease is not peculiar to any one section of Canada or the United States but has appeared in the North, in the South, in the East and in the West. In the opinion of our medical staff, the symptom complex which appears in Toronto is essentially the same as that which exists in other parts of the country. Our conclusions, obviously, are based on the type that we have seen.

The study of this disease has been pursued in many ways at the Hospital for Sick Children, Toronto, for the past five years. Each year details have been discovered that were unobserved in the previous year's study and new avenues for research have been considered and followed. The subject is still being investigated and at the present time a large staff is occupied with various lines of research. Much valuable information has been amassed in this time. The present paper deals more particularly with the otologic aspects of the problem. A preliminary report on the medical aspects of the problem has recently been presented by Dr. Alan Brown, physician-in-charge of the hospital, before the Southern Medical Association. He described the disease as follows:

> Acute intestinal intoxication is a distinct clinical entity. The condition is characterized by three cardinal signs and symptoms; namely, diarrhea, vomiting and drowsiness.
>
> The history usually obtained is that the illness starts with diarrhea, followed by vomiting and drowsiness. The vomiting occurs two to ten times a day. The stools, which are five to ten a day, are loose and watery and sometimes contain mucus, but not the pus and blood seen so frequently in dysentery. The degree of drowsiness varies even in the same infant. In the mild and moderately severe cases the infant may appear quite bright when aroused. Even the disturbance produced by undressing the infant may be sufficient to dispel any evidence of drowsiness. For this reason the patient should be carefully observed before being disturbed in any way. When aroused the infant has a shrill, piercing cry, although in the severe cases the cry may be only a weak moan. The temperature rarely exceeds 102 or 103 F. The color of the skin is ashen gray, the eyes are sunken, the hands and feet are cold and clammy and either cyanosed or gray in color. Dehydration is invariably present, as shown by loss of elasticity of the skin. The liver is usually enlarged. In many instances infections of the upper respiratory tract, including the ears and mastoids, are encountered.
>
> The condition occurs not only in the undernourished marantic infant with a history of previous gastro-intestinal disturbances, but likewise in infants of normal weight with no history of previous trouble. It is a disease chiefly of the free dispensary class, being rarely encountered in well-to-do families, although we have seen an occasional case in this latter group.
>
> The course of the disease may be very rapid, some infants dying within twenty-four to forty-eight hours of the onset of drowsiness in spite of any treatment employed. In other cases the drowsiness disappears and the vomiting ceases within twenty-four hours of the institution of treatment and the infants make an uneventful and usually rapid recovery. The remaining patients continue to vomit slightly and are drowsy for many days before they make the turn one way or the other. The mortality in the severe cases is very high, being well over 50 per cent. This is irrespective of the previous nutrition of the infant. In fact, the large, rather fat infant frequently shows the least resistance to the disease.

Appearance of infant suffering from typical acute intestinal intoxication.

> The pathological findings recorded have given little help as to the etiology of the condition. No consistent pathological changes have been recorded.
>
> Many theories have been advanced in recent years as to the etiology of acute intestinal intoxication, such as: (1) the production of some toxic substance from the food by decomposition; (2) improper foods; (3) infection of the intestinal wall with bacteria, or (4) abnormal absorption of catabolites from the bowel. Numerous bacteriological researches have failed to reveal a pathognomonic organism.

THE MASTOID INFECTION THEORY

A more recent theory has, however, thrown suspicion on the mastoid antrum as the etiologic factor.

A study of the extensive literature on the subject shows that a number of facts have been observed, a number of assertions made, and certain deductions drawn regarding the connection of mastoid antrum.

* Owing to lack of space, this article is abbreviated in The Journal by the omission of a bibliography. The complete article appears in the author's reprints.

[1] Coates, G. M.: Mastoid Infection in the Infant, Ann. Otol., Rhin. & Laryng. 36: 913 (Dec.) 1927.

infection and the disease. The argument has been developed much as follows:

1. At autopsy on infants dying from acute intestinal intoxication:
   - (*a*) No evidence of gastro-enteritis has been discovered.
   - (*b*) Accumulations have been found in the ear cavities.
   - (*c*) Cultures from these accumulations have yielded organisms.
2. During the course of the disease:
   - (*d*) Otitis media has been observed.
   - (*e*) If not observed, the presence of infection has been established by incision of the ear drums,
   - (*f*) or, if necessary, by antrotomy.
   - (*g*) Mastoiditis, obvious or latent, could be inferred.
   - (*h*) A simple mastoidectomy or antrotomy would demonstrate the presence of antrum infection, and afford the patient much greater opportunity of recovery.
3. Hence it has been argued that the infection found in the mastoid antrum:
   - (*i*) was the cause of vomiting, diarrhea and drowsiness,
   - (*j*) was the cause of the acute intestinal intoxication.

Each of these points has been carefully considered in our observations.

METHODS OF INVESTIGATION

An outline of the method of investigation used will now be given, but to avoid repetition it is necessary to make a few preliminary remarks.

The term "infant" is used to designate a child 24 months of age or less.

The facts and figures used are drawn from an elaborate study of all pertinent records for five consecutive years, from 1925 to 1929 inclusive, at the Hospital for Sick Children, Toronto.

The statistics and conclusions have the consideration and approval of the physician-in-chief, and his research department and the pathologist and his department.

The relationship of infection of the paranasal sinuses is not considered in this report.

In the earlier years, aspects of the subject were studied from time to time with the object of proving certain preconceived ideas regarding it. At the outset there appeared to be adequate support for the contention that cloudy material in the mastoid antrum was the etiologic factor in this disease. The conclusion did not meet with the unanimous approval of the staff of this hospital, on the ground that the work was done on too small or too specialized groups of patients.

Realizing the defects of the previous work and the many-sidedness of the subject, eighteen months ago we planned a comprehensive "investigation of infants suffering from this disease, which investigation has been in progress since that time." Certain workers were allotted to the observation of particular parts of the investigation. The clinical and chemical observations were undertaken by the physician-in-chief and two of his clinicians. An experienced bacteriologist undertook the bacteriologic examination of the blood, stools, urine and upper respiratory tract as well as the serologic tests. Three other members of the research department studied the blood volume, the capillary blood flow and the sugar tolerance. The department of pathology gave the autopsies special consideration. The attempt was made and still is being made to study every aspect of the disease without bias.

During the period when acute intestinal intoxication was epidemic, every infant exhibiting on admission the three cardinal signs and symptoms of vomiting, diarrhea and drowsiness was at once examined by a constant group of observers. The observations and the conclusions of all were dictated on the spot to a stenographer. The ears, nose and throat were minutely examined. The nasopharyngoscope was invariably used. Swabs for culture were taken from the nose, nasopharynx, ears and throat with rigid regard to care against contamination. Repeated examinations at later dates were similarly made. If the patient succumbed, an earnest attempt was made to secure an autopsy, and if that was successful great care was taken in the observations on the temporal bone.

FACTS REVEALED BY ROUTINE AUTOPSIES

Material Available for This Investigation.—Study of the autopsies in the earlier years of the investigation revealed the fact that the head had been examined in a disappointingly small percentage of instances. From the commencement, therefore, of the comprehensive investigation, effort has been made to get permission for the examination of the head at postmortem.

Table 1 shows the number of patients handled in our infant ward in the past five years, the number of deaths, the number of autopsies and the number of instances in which the head was examined.

The Infant Antrum at Autopsy.—The conception that suppuration of the ear was the essential factor in the infant mortality of this disease had its origin in the observation that at autopsy accumulations of pus or cloudy fluid were found in the mastoid antrums. Other observers had suggested that this material would be found in all mastoid antrums a few hours after death; suggesting, therefore, that the accumulations were a postmortem change.

Table 1.—*Autopsies on Infants 24 Months of Age and Under*

Year	Total Number of Admissions to Infant Ward	Total Deaths	Total Autopsies (Excluding Those Dying in the First Few Days of Life)	Total Number in Which the Heads Were Examined
1925	1,223	333	110	27
1926	1,217	367	84	39
1927	1,254	328	111	68
1928	1,247	365	136	100
1929	1,429	431	177	90
Total for five years	6,370	1,814	618	324

It was, therefore, necessary to discover evidence regarding this point. To do this, the autopsies of all patients 24 months of age and under for the past five years have been examined. Out of 324 autopsies on the head, 199 showed both mastoids healthy, 49 showed one mastoid with fluid in it and 75 showed material in both mastoids (table 2).

The relationship of these figures to the number of hours after death that the autopsy was performed was also studied. Of the cadavers showing healthy mastoids 114 were examined from one to ten hours after death, 50 from eleven to fifteen hours after death, 21 from sixteen to twenty hours after death, and 14 twenty or more hours after death.

This conclusively proves that the mastoid antrums of infants are as a rule healthy and that with due care they may remain so for many hours after death. It can therefore be inferred that accumulations or infections found in the mastoid antrums of infants at autopsy, provided the cadaver was at once put in cold storage, are ante mortem in origin.

FACTS REVEALED FROM CLINICAL INVESTIGATION

Analyses of the records of patients suffering from acute intestinal intoxication in the first three years are not given because there were so many errors and omissions that the members of the staff have not been able to agree on the conclusions, but, as previously stated, in 1928 and in 1929 two long series of cases were studied so carefully that there is unanimity regarding the figures quoted.

Gross Observations at Autopsy.—Series of 1928: In 1928 eighty-three infants were critically studied, and forty-one cases were finally classified as acute intestinal intoxication. Twenty of the forty-one patients died. Autopsies on the head were performed on five (table 3).

In all of them evidence of an intestinal infection was found. In two, slight evidence of pathologic change was found in the antrum or its immediate periphery only; there was no involvement of the greater part of the mastoid; pure cultures of hemolytic streptococcus and *B. hoffmanni* were obtained. In three there was no mastoid infection.

Therefore the autopsies on this series show that mastoid infection was not the primary cause of the intoxication.

Series of 1929: In 1929, 158 infants were critically studied; 127 cases were finally classified as acute intestinal intoxication. Fifty-six of the latter patients died. Autopsies on the head were performed on fifteen.

In all of them evidence of an intestinal infection was found.

Of the six cadavers showing mastoid involvement, two showed minute change in one mastoid only, and four had considerable purulent material in both mastoid antrums. In nine of these there was no mastoid infection.

Therefore the autopsies on this series show that mastoid infection was not the primary cause of the intoxication.

Bacteriology.—The incidence of hemolytic streptococci in the upper respiratory tract of the two series showed considerable similarity in spite of the inequality in number.

The control series of 1929 showed a higher percentage of hemolytic streptococcus changes in throats than the series of 1928. This was rather surprising, since some control studies were conducted during the colder weather in that series whereas the series of 1929 was studied entirely in the warmer months of the year (table 4).

The presence of streptococci in the nose and throat then has little significance, since it has not the seasonal incidence to correspond with that of acute intestinal intoxication. Moreover, the presence of hemolytic streptococci in both case and control studies further weakens the possibility of their etiologic significance. Again, upper respiratory infections, if of causative importance, should be produced by a uniform flora; this was not the case.

In only five of the 1928 series was the organism picked up from the nose or throat the same as that picked up from the ear. In all other cases there was no correspondence between the organisms grown from swabs from the nose and throat and those from the ear.

Table 2.—*Conditions Found in the Mastoids of Infants at Autopsy*

						Relation of Age to Condition of Mastoid										Relation of Hours After Death That Autopsy Was Performed to State of Mastoid

Cultures were also made from the stools; in only two of these was an organism picked up from the nose, throat or ear the same as the organism picked up from the intestine. There was, therefore, no correspondence between the bacteriology of the infection in the upper respiratory tract and that in the intestinal tract.

Each available serum was tested for its agglutination power against organisms of possible pathogenic significance found in the stool. In the series of 1928, the blood showed positive agglutination power in nine infants against an organism found in the stool. In twenty-three cases, agglutinins were demonstrated for one of the allied group of intestinal organisms. There was, therefore, surprising evidence of reaction on the part of the blood stream to the infection found in the intestinal tract.

While the serologic work on the series of 1929 is not completed, the evidence that the infection is primarily intestinal seems to have even firmer basis.

About one third of the serums have given marked agglutination with *B. dysenteriae* Sonne, while other serums have yielded suggestive results with other bacterial species.

The Type of Infant Exhibiting Acute Intestinal Intoxication.—The reader is referred to a paragraph on this point by Dr. Brown,[2] already quoted. A combined table shows that 117 infants were described as well nourished and 51 as poorly nourished.

First Symptoms.—For a considerable period the medical officer admitting to the infant ward has had a routine series of questions regarding the patient's history to which he must obtain a reply at the time of the admission. One of these reads, "Did the present illness start with a cold?" Our tables show a "cold" as the initial symptom in only 22 out of a total of 168 cases. Indeed, it is remarkable that a large proportion of these histories read, "Did not have a cold before the illness began and no member of the family had a cold."

Condition on Admission.—The majority of the patients were toxic at the time of admission. Attention is drawn to the remarkable number in whom no signs of nasopharyngeal or aural infection could be noted. It constitutes an argument in favor of the conception that upper respiratory infection is not the essential cause of acute intestinal intoxication.

That certain other infants—a very small number—developed typical acute intestinal intoxication signs and symptoms in the hospital with coincident upper respiratory infection in no way detracts from the foregoing deduction.

Attention is also drawn to the exceedingly small number of infants in this series who exhibited enlargement of the cervical glands.

Ear Drums Normal Throughout Illness.—The most striking clinical observation is the frequency with which an infant is admitted in an extreme state of acute intestinal intoxication without any evidence of infection in its ears, nose or throat. Table 3 shows that out of 168 admissions, 111 had no demonstrable ear, nose or throat infection. It shows that 63 had no ear infection and 130 had no nasal infection during the course of their stay in the hospital. It also shows that of the 20 infants who came to autopsy, 9 had no infection in either ear and 12 had no infection in either mastoid. Two infants developed clinical mastoiditis during their stay in the hospital. It is therefore reasonable to assume that ear or mastoid infection could not be the cause of the acute intestinal intoxication.

Ear Drums Normal Until Just Before Death.—Reference has been made to the fact that in a considerable percentage of the 168 cases of acute intestinal intoxication in 1928 and 1929 both ear drums were normal at the last recorded examinations, and that, in a number of patients who died, middle ear abnormality was not detected at autopsy.

In the accompanying tables, the remaining ears have been classified as infected. But this does not mean that all these were infected—it does mean that they all showed an observable change from the normal.

In making these observations it was remarkable how shortly before death the ear drums, which had up to then maintained their normal luster, would change to a grayish color with complete loss of luster, and a very slight fulness would appear in the posterosuperior quadrant, rarely obscuring at all any part of the malleus. The condition was usually the same in the two ears. Sometimes incision of this bulge resulted in the escape of a drop of cloudy material that occasionally produced an organism on culture. The colon bacillus was found in the ears of five infants of the series of 1928.

Even when the culture has been positive, I do not believe that the observed change postulates infection. There is absolutely no evidence in the tissues of reaction to infection. The tissue cells are dying; they are incapable of response. At the same time the eyes of the patient are glassy and sticky; the mouth is dry; the patient is dying. The peculiar appearance of the drum head is but a part of the general anhydremic picture.

Several times at autopsy the pathologist has described stomach contents in the nasopharynx and the same material in the eustachian tubes and middle ears and on one occasion he demonstrated bile in the middle ears. It may be remarked once more that this middle ear condition is, as a rule, bilateral.

I am therefore of the opinion that this change is an antemortem phenomenon due to the forcible ejection by sneezing, crying, coughing or vomiting of pharyngeal contents up eustachian tubes which have lost their resilience. When mastoid infection exists, it is the result and not the cause of the child's lowered condition.

---

[2] Brown, Alan, et al.: Etiology of Acute Intestinal Intoxication of Infants, Preliminary Report, South. M. J. 23: 107 (Feb.) 1930.

Otitis Media Developing During Illness.—It is exceedingly easy to produce abnormal appearances in an infant's ear drum by manipulation. It is essential, therefore, that, in the investigation of such a problem as this, the examination and care of the infant's ears should be in the hands of a careful otologist.

In spite of such care, it is widely admitted that an overwhelming majority of infants sick in an infant ward for any length of time develop otitis media in one or both ears. Middle ear infection is of frequent occurrence in infants, particularly in those with lowered resistance from acute or chronic disease.

In table 3 it is shown that in 105 (62 per cent) of 168 cases of acute intestinal intoxication one or both ears became infected while in the hospital; and that in 47 of the 73 control cases (64 per cent) one or both ears were infected. Therefore the incidence of otitis media was no greater in the acute intestinal intoxication group than in the remainder. The controls were not a great number. The exact incidence of otitis media is difficult to obtain in any really active children's hospital. A general statement may be made, however, that middle ear infection occurs in those patients who remain a long time in the hospital just as frequently as it does in those suffering from acute intestinal intoxication or perhaps more frequently.

Another observation acceptable to all is that ordinary infants with otitis media are irritable or slightly drowsy but not toxic.

I do not believe that chronic mastoiditis can exist in an infant without apparent evidence in the middle ear.

Observations from the Autopsies.—The statement has been made by several writers that in recent years all patients presenting the clinical picture of acute intestinal intoxication have mastoiditis, paranasal sinusitis or both as the underlying cause of their disturbance.

My experience (table 3) is quite different. One hundred and eleven patients presented the typical picture of severe acute intestinal intoxication without any demonstrable upper respiratory infection.

Mastoid Antrum Puncture for Diagnosis.—Following a suggestion that the mastoid antrum of the infant could be safely aspirated for diagnosis or latent infection, Dr. L. J. Dill and Dr. C. E. Snelling did the procedure according to the technic advised. They performed the operation only on cadavers and immediately prior to autopsy. Their conclusion from a series of sixty-six punctures is that the procedure is neither safe nor infallible.

Observations from Operation.—It has been stated that mastoid operation or antrotomy has been effectual in stopping the course of the disease. While this study was being pursued, thirteen patients were submitted to operation on both mastoids. These were all severely toxic and presented no clinical evidence of mastoiditis. The operations were distributed among the otolaryngologic staff. Every care was taken in the technic. A few operations were done under a general anesthetic, but the majority under a local anesthetic. The postoperative care was carried on by the operator. As a result of this painstaking work, I believe that, in spite of the fact that these patients were very poor operative risks, no child's death was in any way hastened by the operation.

Cloudy material was found in the antrums of nine of these thirteen infants. In some the mastoid wounds healed satisfactorily before death and in others the wounds were in the course of healing. Eventually, however, only one recovered. I believe that this constitutes considerable evidence in favor of the view that the mastoid infection was not the cause of the toxemia.

The united view of the staff of this hospital is that none of these mastoid antrums or mastoids showed the picture of reaction of the bone cells to infection which we are accustomed to see in acute mastoiditis. Pus we admit. Swelling and infiltration of the mucosa we admit. Also some cloudy material in a few small cells at the periphery of the antrum. But not typical mastoiditis. There was so little evidence of local trouble in our cases that we do not believe that such a small latent infection trapped in the antrum can be accountable for such profound general symptoms.

Operation is indicated if an infant has typical mastoiditis; but operation is not necessarily urgent, even in the presence of an acute streptococcic infection. The average infant suffering from acute intestinal intoxication is close to death, and operation is to be avoided if possible. Our medical staff has now seen so many sufferers from this disease with normal middle ears and mastoid antrums that it refuses to allow the mastoids of infants with acute intestinal intoxication to be operated on unless they exhibit true clinical mastoiditis.

Incidence of Intestinal Signs and Symptoms.—It has been held that an infection in the ear may be responsible for diarrhea, vomiting and loss of weight in infants. My impression is that it can cause a mild degree of these, but not the acute type that occurs in acute intestinal intoxication. As a check on this argument, the case histories of all the infants of 2 years of age and under who have had a mastoid operation performed have been studied to see whether diarrhea, vomiting or loss of weight occurred in them. In 133 consecutive cases, one or more of these symptoms was noted in only 18 patients. Vomiting without diarrhea or loss of weight occurred in 9. Diarrhea, but neither vomiting nor loss of weight was found in 1. Loss of weight without diarrhea or vomiting was found in 5. Diarrhea and vomiting occurred in 1. Diarrhea and loss of weight occurred in 1. Vomiting and loss of weight occurred in none. Diarrhea and vomiting and loss of weight occurred in 1.

It was surprising how frequently it was mentioned that the child was somewhat constipated. The vomiting was never severe, and it was generally noticed as a slight regurgitation following a spell of coughing. Our conclusion, therefore, from this control series is that mastoiditis, per se, in infants is rarely responsible for these symptoms.

SUMMARY

1. Many authors believe that infection in the mastoid antrum is the cause of acute intestinal intoxication in infants.
2. Our medical staff believes that the type of the disease seen in Toronto is the same as that which exists in other parts of Canada and the United States.
3. Study of the disease has been pursued seriously for five years. For the last two years a large body of workers have cooperated.
4. The onset of the disease is rarely characterized by a "cold."
5. The great majority of the infants were without any clinical evidence of an upper respiratory infection at the time they were toxic.
6. Many infants remained without any ear infection throughout the whole course of the illness.
7. Accumulations or infections found in the mastoid antrums of infants at autopsy are ante mortem in origin.

8. Both ear drums of many showed abnormality immediately preceding death. This change is an antemortem phenomenon due to forcible ejection up to the eustachian tubes. When mastoid infection exists, it is the result and not the cause of the child's lowered condition.

9. Mastoid antrum puncture for diagnosis of latent mastoiditis is not to be recommended.

10. Bilateral mastoid operation as a cure for the disease was a failure. Operation is to be postponed as long as possible.

11. The autopsies of the two intensively studied series of cases of acute intestinal intoxication show that mastoid infection was not common.

12. There was no correspondence between the bacteriology of the infection in the upper respiratory tract and that in the intestinal tract.

13. Evidence is being accumulated to show that the disease is of intestinal origin.

CONCLUSION

Infection of the mastoid antrum is not the cause of acute intestinal intoxication in infants.

SCURVY IN ADULTS

ESPECIALLY THE EFFECT OF FOOD RICH IN VITAMIN C ON BLOOD FORMATION *

STACY R. METTIER, M.D.,

BOSTON

Scurvy in adults in large centers of population is infrequent but not rare. Outbreaks occurred among both the civil and the military population of certain countries[1] during the World War, but since 1920 only reports of a single case or small groups of cases appear in the literature.[2] Öhnell[2] and Shattuck[2] remark that the disease is perhaps more frequent than is supposed and that cases, especially in latent form, often are not recognized. Nine cases of scurvy in adults, eight of which were males, have recently come under our observation. The occurrence and certain precipitating factors of the disease, together with observations on the alleviation of the anemia of scurvy, comprise the subject matter of this paper.

OCCURRENCE OF SCURVY AND CERTAIN PRECIPITATING FACTORS

With the single exception of Öhnell,[2] who records the occurrence of scurvy in sixteen females out of the twenty-two cases he observed in Sweden, the other recent reports[3] concerning scurvy in adults deal largely with males over 50 years of age; men who live alone and whose subsistence depends on their own culinary inclinations. Meulengracht[2] defines the condition as "bachelor scurvy." This was essentially the state of affairs for seven of our eight male patients who were all over 50 years of age. The diets of our patients had been ones prepared largely from flours and often composed of food purchased at a store in a form ready to eat. These diets contained little or none of the foods rich in vitamin C; i. e., vegetables, fruits and certain animal tissues.

Poverty plays an important rôle in the choice of diet, although aversion to foods rich in vitamin C may be the reason given for an abnormal diet. Of rather rare occurrence is the development of scurvy from a prolonged strict diet provided for an organic disorder such as duodenal ulcer. Davidson[2] has reported such an instance. Our female patient developed scurvy seven years after being placed on a milk and cracker diet for gastric ulcer when 27 years old. She developed a psychosis and, although the symptoms associated with ulcer vanished, she continued to take a diet similar to the one originally prescribed. Another patient chose for over a year an ill balanced diet sparing in fruits and vegetables. He then took of his own volition, because of a tendency to diarrhea, a diet consisting of only boiled milk and white flour biscuits ("Uneedas"). The patient continued this regimen for about a month, when he developed acute bronchitis. As the bronchitis subsided, slight but definite signs of scurvy developed. They rapidly disappeared when he was given an appropriate antiscorbutic diet. A single instance is reported in the literature in which scurvy followed persistent vomiting in pregnancy.[4]

It is important to appreciate that ill health may be produced by the deficiency of a food factor in much smaller amounts than that necessary to create the typical syndrome associated with its lack, as has been so well discussed by McCollum.[5] It is recognized that conditions due to vitamin deficiencies and due to a lack of certain hormones are brought forth or intensified under various adverse conditions. Infectious processes, chronic fatigue and excesses of various sorts may precipitate a deficiency disorder when states of nutritional instability are present. Individuals with nutritional instability may have the appearance of health but usually lack a normal sense of well being. Infections undoubtedly can precipitate in such persons typical syndromes of a deficiency disorder and probably more often conditions that are not well recognized as being due to abnormal nutrition. An instance of scurvy being

brought forth by an infection has already been cited in the case of the patient who developed bronchitis. A similar reaction has been noted in the experimental scurvy of guinea-pigs.[6] Another clinical example is as follows: A man, aged 60, entered the hospital because of bronchopneumonia and a fractured rib resulting from a recent injury. He was somewhat overweight and did not have the appearance of chronic ill health. The day after admission there developed a large ecchymosis over the left flank extending to the region of the broken rib. At this time the ecchymosis was thought to be dependent on the recent injury. The following day, however, a similar large area of ecchymosis appeared in the right flank, and a few hemorrhagic lesions appeared on the gums and about the buccal mucous membrane. Similar lesions also developed on the lower part of the right leg. It was then learned that for years his diet had consisted chiefly of coffee, pastry, potato, and bread and butter, with only small amounts of meat or fish, and that he ate but rarely green vegetables or fruit. He was given about 400 cc. of orange juice daily, together with a diet composed chiefly of concentrated carbohydrate food of the variety containing little or no vitamin C, and within a week the lesions attributed to scurvy entirely disappeared. Cases of this sort, in which an infection brings forth a definite syndrome because of an inadequate supply of a dietary factor for a prolonged period of time, are unusual, but serve to emphasize the importance of a well balanced diet with optimal amounts of all food factors for the maintenance of health.

The presence of arteriosclerosis in individuals partaking of an ill balanced diet for a long time may perhaps favor the development of a deficiency disorder. There is some evidence at hand to suggest that pernicious anemia and pellagra patients with arteriosclerosis are apt to require greater amounts of effective substance to alleviate their deficiency than similar patients with normal blood vessels. It has been suggested[7] that arteriosclerosis may enhance the development of scurvy, particularly in elderly men partaking of suboptimal amounts of vitamin C, because it was noted to be a feature of many cases of scurvy in adults. Cardiovascular damage, chiefly arteriosclerotic in type, was present to a greater or lesser degree in all of our recent eight cases of scurvy in elderly males. Perhaps thickening of the blood vessels prevents the tissues from receiving nutritious elements as readily as when such a condition is absent.

It is, of course, difficult to diagnose cases of "latent" scurvy unless some infectious process or other circumstance occurs that precipitates the typical disease. It is suspected, however, that cases of scurvy in adults occur more frequently than is commonly recognized and will be detected if relatively minor symptoms, such as poor appetite and loss of energy, are looked for and the dietary history is carefuly evaluated.

THE ANEMIA OF SCURVY

A study of the literature shows that anemia of variable degree occurs in a large percentage of adults with scurvy. It also occurs in infantile scurvy and is of regular incidence in the experimental scurvy of guinea-pigs.[8] Scurvy in adults is apt to develop following a prolonged period of nutritional instability and thus manifest a chronic condition. Chronicity apparently favors the production of anemia. Our observations on the blood are in accord with those of numerous other physicians.[9] In a large group of cases of scurvy in adults one may expect to find about 35 per cent with red blood cell counts between 2 and 3 million per cubic millimeter, a similar number with between 3 and 4 million red blood cells per cubic millimeter, and the remainder showing slight or no anemia with red blood cell counts above 4 million per cubic millimeter. The hemoglobin is reduced so that a color index of about 1 is the rule. Achromia of the red blood cells is not a feature, but slight central pallor of these cells is frequent. If hemorrhage has been an important factor in the production of the patient's anemia, a greater degree of achromia and a lower color index will occur. Abnormal variation in size is more pronounced than variation in shape. Occasionally there may be a sufficient number of nonachromic cells slightly larger than normal to suggest the possibility of pernicious anemia. About 1 per cent of the cells are usually polychromatophilic, and nucleated erythrocytes may appear in the peripheral blood. The blood platelets occur in from normal to moderately increased numbers. The leukocytes in uncomplicated cases are usually between 4,000 and 6,000 per cubic millimeter. A slight lymphocytosis with about 3 per cent atypical lymphoid cells frequently occurs. Monocytes are not increased. A few myelocytes are often to be observed. Polymorphonuclear eosinophils are not absent but basophils are seldom present.

It is well known that an antiscorbutic diet causes the anemia to lessen and to do so frequently with amazing rapidity, but there appears from the literature to be some confusion as to the exact reason for anemia in scurvy. Undernutrition and intercurrent infection have been held to be,[10] and undoubtedly are, contributing factors. Loss of blood, especially from the intestinal tract, has been considered by some individuals as the most important cause for the anemia. However, since anemia occurs without evidence of hemorrhage of large amount, some other factor would seem to be fundamental. The observations given farther on lend support to the idea that the anemia may be due to insufficient red blood cell production, as Hojer[8] and others have suggested. Our observations furthermore suggest that the inadequate function of the bone marrow may be directly dependent on a chronic lack of vitamin C, although in any given case some other factor or factors may intensify the process.

OBSERVATIONS ON THE RESPONSE OF THE RETICULOCYTES AND TOTAL RED BLOOD CELLS

Foods rich in vitamin C can rapidly effect erythropoiesis in scurvy for we have observed five cases in which a definite rapid increase of the reticulocytes occurred as a response to a diet rich in this vitamin. Data relative to the first patient, recorded in figure 1, show that the reticulocytes began to increase on the third day after he partook of a diet that was chiefly composed of fruit and green vegetables and that contained no animal food except boiled milk. They reached the peak of their rise on the eighth day and returned to normal by the fifteenth day. The response of this patient's reticulocytes was entirely similar to that observed in a second patient treated in a similar manner and in three other patients treated as described later on. Figure 2 shows the response in one of these other patients. The reticulocytes in all instances began to increase on the third or fourth day and then reached the peak of their rise on from the fifth to the eighth day. The height of their rise probably depends in some measure on the amount of potent material fed, the degree of anemia and the precise state of the patient. This state of affairs is comparable to what occurs with the administration of potent substances in pernicious anemia.[11] The response of the reticulocytes was coincident with cessation of hemorrhage in the scurvy patients. There was associated with this reaction of the bone marrow an increase of the red blood cells which usually continued rapidly to a normal level concomitant with a pronounced improvement in the health of the patient.

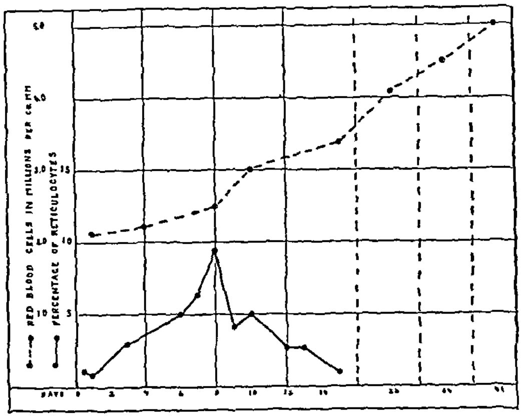

Fig. 1.—Response of the reticulocytes to a diet rich in fruit and green vegetables, without liver or iron, in a case of scurvy in a man.

Certain anemias, appropriately called dietary anemias because they are associated with the patient partaking of an inadequate diet for a prolonged period of time, chronic chlorosis, and anemias of ill defined origin particularly occurring in women and often associated with gastric anacidity, as well as some other anemias, such as those due to chronic blood loss, lessen rapidly following the administration of large doses of iron. Therefore, it was thought that the anemia of scurvy might be alleviated by suitable iron therapy, and, like patients with anemia benefited by iron, might show a prompt response of reticulocytes to this element. Accordingly, two elderly male patients with typical scurvy were treated as follows:

They were given daily a diet deficient in vitamin C, composed of boiled milk and white flour biscuits. During six days there was no change in their reticulocytes. Then for six days in one case and for seven days in the other, 6 Gm. of iron and ammonium citrate (U. S. P.) were added to the diet. When the iron was omitted the same diet was continued but with the addition each day of 575 cc. of orange juice.

The results that occurred in the first patient given this treatment are recorded in figure 2. There was no significant quantitative change in the circulating reticulocytes within eight days following the commencement of iron therapy. However, after the patient had enjoyed the fruit juice for three days the reticulocytes began to increase from a stationary level of about 2.5 per cent. They reached a level as high as 9.7 and 9.9 per cent on the fourth and fifth day, respectively, and then rapidly fell to a low level during the following three days. During the twelve days that the patient took food lacking in vitamin C there was a drop in the hemoglobin from 73 to 55 per cent, and the red blood cells fell from 3.8 to 2.5 million per cubic millimeter. Striking, rapid improvement, however, occurred soon after the administration of orange juice, so that in twenty-four days after the patient first received this fruit juice the red blood cells were 4 million per cubic millimeter and the hemoglobin was 90 per cent.

The results obtained in the second case were similar. However, the anemia increased very little during the thirteen days that food lacking in vitamin C was taken by the patient. The reticulocytes increased from a stationary level of about 1 per cent, maintained for six days before and ten days after the commencement of iron therapy, to 3 per cent on the third day that orange juice was given. Their rise persisted so that there were between 4 and 5 per cent on the sixth, seventh and eighth days, followed by a return to a low level on the twelfth day. There was slow but progressive decrease of the anemia, and after forty-one days of an antiscorbutic diet the patient's hemoglobin had increased from 55 to 83 per cent and the red blood cells from 2.1 to 3.8 million per cubic millimeter. The relatively slight response of this patient's reticulocytes, especially in view of the relatively low level of his red blood cells and the continued retarded production of blood that followed, can be attributed to the fact that the patient suffered from cystitis, hypertension, arteriosclerosis and a mild degree of lead intoxication. Infections and poisons are known to inhibit the response of the bone marrow to substances potent for a given type of anemia. The four other patients whose reticulocytes were observed to respond to food rich in vitamin C had no complication except moderate arteriosclerosis. There was a rapid but temporary increase of reticulocytes in these four patients with a quick regeneration of hemoglobin and red blood cells. Apparently a maximal production of reticulocytes occurred because they increased to the same approximate numbers as are found at comparable red blood cell levels in pernicious anemia following the administration of optimal amounts of effective material.

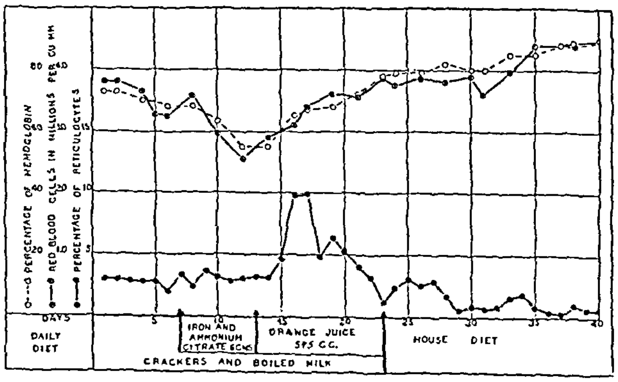

Fig. 2.—Absence of significant quantitative alteration of the reticulocytes to large doses of iron, but a distinct prompt response following the administration of orange juice, in a case of scurvy in a man.

There are several reasons why one may attribute the reticulocyte response in the two patients given iron and later food rich in vitamin C to material contained in the food rather than to a delayed reaction to iron. In the first place, observations on more than twenty-five patients in this clinic and studies by Schulten [12] and by Keefer and Yang [13] as well as by others indicate that when the red blood cells are below 3 million per cubic millimeter the response of the reticulocytes to even considerably smaller doses of iron than our patients received will commence within eight days and usually within five days after iron therapy is started. More than eight days had passed after iron had been given before the reticulocytes started to rise in either of the two scurvy cases. In the second place, if the response to iron is delayed, the reticulocytes do not reach the peak of their rise rapidly, as occurred in the first case. The relatively weak response in the second case sustained over a longer period of time was not a delayed response and is the type of response to be expected when suboptimal amounts of potent material act on the bone marrow or when the effect of optimal amounts are inhibited by infection or other complications. Furthermore, the response of the reticulocytes in these two patients is entirely comparable to that in each of the other two scurvy cases in which the reticulocytes were observed daily and which responded to food rich in vitamin C and to that in one case to be referred to treated with liver pulp.

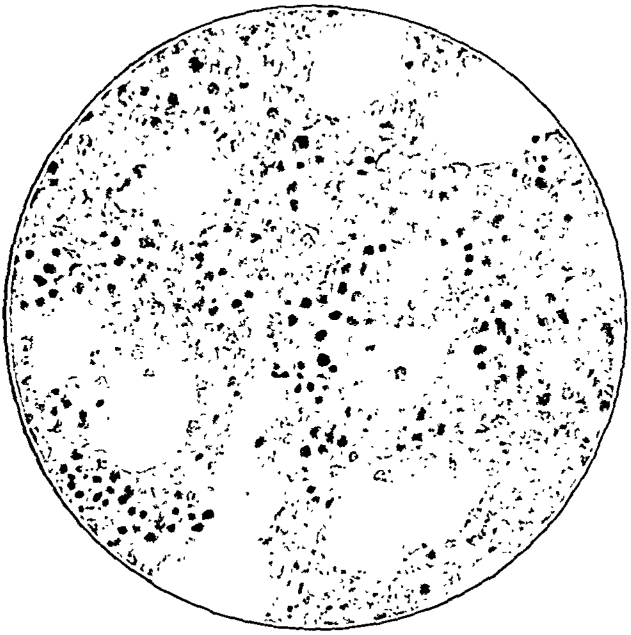

Fig. 3.—Appearance of bone marrow from an elderly man with scurvy; reduced from a photomicrograph with a magnification of 400 diameters. There are scattered foci of nucleated red blood cells and a moderate number of fat cells.

A liver extract potent for pernicious anemia was prepared in such a way that it could not contain vitamin C. This material was shown to be ineffective on the anemia of scurvy. Two patients, on a scurvy producing diet, with red blood cell counts of about 2 milion per cubic millimeter, showed no response of their reticulocytes and showed a slight decrease in the total number of red blood cells during ten days when they were each fed sufficient liver extract to cause a prompt response in pernicious anemia. The feeding of 240 Gm. a day of fresh raw liver pulp promptly produced a reticulocyte response with 8 per cent reticulocytes at the peak of their rise, and produced rapid regeneration of red blood cells in one of the cases, which is attributed to the fact that fresh liver is rich in vitamin C. The anemia of the other patient lessened rapidly when he took an ordinary well balanced diet containing plenty of vitamin C.

The observations recorded indicate that food rich in vitamin C can cause a prompt response of the reticulocytes and a rapid regeneration of blood in scurvy, and evidence favors the conception that neither large doses of iron nor the substance effective in pernicious anemia can do so. This information lends support to the idea that the fundamental cause of anemia in scurvy is the lack of vitamin C in the diet, although undoubtedly hemorrhage, infection, undernutrition and other factors may complicate the picture. It would appear, thus, as if vitamin C rather specifically affected the bone marrow of the patient with scurvy.

THE BONE MARROW IN SCURVY

There are only a few accounts in the literature of the state of the human scorbutic bone marrow. In their textbooks, MacCallum,[14] and Naegeli [15] described the bone marrow as having lost its blood-forming elements and as having become converted into an edematous fibrous tissue. Vedder,[16] on the other hand, states that the bone marrow is consistent with the type seen in secondary anemia from many causes. He writes that the fat disappears and that the marrow shows marked cellular hyperplasia.

Before treatment a specimen of sternal bone marrow was obtained by bone marrow puncture from the second patient given iron. A photomicrograph of this bone marrow is reproduced in figure 3. The tissue shows moderate cellular hyperplasia and contains a few isolated fat cells. There are scattered small varying-sized groups of nucleated red blood cells. Many myelocytes are present, among which are several of the eosinophilic variety. Adult polymorphonuclear leukocytes and megakaryocytes occur in moderate numbers. There is no evidence of fibrosis.

A specimen of sternal bone marrow was also removed at the peak of the reticulocyte response from the second patient, treated with only a diet rich in vitamin C. This specimen, pictured in figure 4, in contrast to the one shown in figure 3, shows quantitatively more nucleated red blood cells. Mitotic figures among the precursors of these cells were not apparent in the specimen (fig. 3) obtained from the patient prior to any treatment, whereas, in the specimen obtained at the time of the peak of the reticulocyte rise, a few mitotic figures appear in each field of the microscope.

Thus the bone marrow alterations depicted by these two specimens are characteristic of what is spoken of commonly as secondary anemia. No definite conclusions, of course, can be drawn as to the comparative histology of the bone marrow before and during treatment; but the character of the bone marrow suggests the possibility that when vitamin C has been chronically deficient its replenishment in the body can promote in some fashion the development of nucleated erythrocytes. In pernicious anemia, potent material apparently permits maturation of the megaloblasts in the bone marrow.

which leads to a reticulocyte response. In scurvy and in anemias responding to iron perhaps the effective substance hastens maturation of the normoblasts, which, under comparable conditions, permits a reticulocyte response that we have noted tends to occur somewhat more rapidly than in pernicious anemia. The increased rate could be accounted for by the fact that the normoblast is a less primitive cell than the megaloblast, so that the former could maturate sooner than the latter. At all events, the increased activity of the bone marrow in scurvy is clearly reflected in the peripheral blood by the reticulocyte response to food rich in vitamin C.

Knowledge has been advanced rapidly in recent years concerning the importance of food in alleviating anemia and the influence of inadequate diets and digestive processes in the causation of anemia. Known vitamins play no rôle in the regeneration of the blood in pernicious anemia, and at least are not required for regeneration of blood in many cases of secondary anemia. If, however, an anemia can be related to a vitamin deficiency, it oftentimes will be decreased by the administration of material rich in the vitamin, the lack of which occurs in the given patient. Such appears to be the case in pellagra, in chronic vitamin A deficiency and in scurvy.

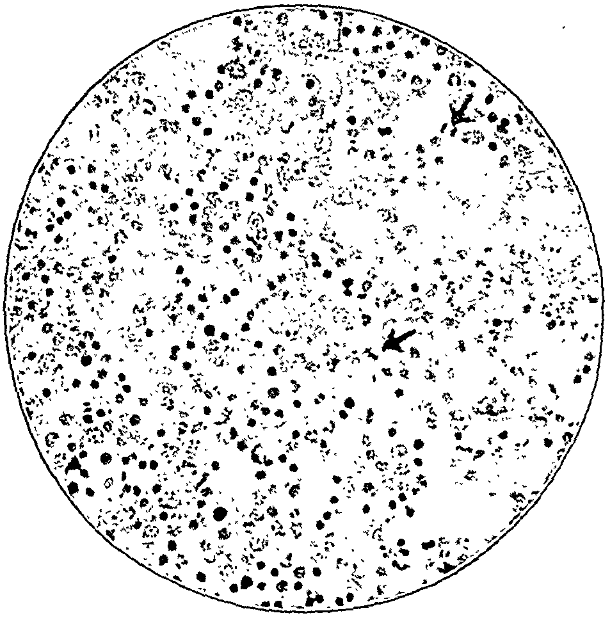

Fig. 4.—Appearance of bone marrow from an elderly man with scurvy at the peak of the reticulocyte response induced by orange juice; reduced from a photomicrograph with a magnification of 400 diameters. Note the large numbers of nucleated red blood cells. A few mitotic figures are present among the younger forms, some of which are indicated by arrows.

SUMMARY

Nine cases of scurvy in adults were studied. Eight occurred in elderly males.

Scurvy can be precipitated by infectious processes in individuals with certain types of chronic nutritional instability. Arteriosclerosis may favor the development of the disease.

In adults with scurvy, anemia is common and often pronounced. Fruit, green vegetables and fresh liver, foods which are rich in vitamin C, can cause in these patients a prompt response of reticulocytes and rapid regeneration of blood. Neither large doses of iron nor the substance potent in pernicious anemia appear to accomplish these effects.

The bone marrow in two cases of scurvy was examined microscopically. It appears to be of the type that occurs in what is often spoken of as secondary anemia.

Vitamin C apparently can have a specific effect on erythropoiesis when there has been a chronic lack of this vitamin.

PREGNANCY AND LABOR COMPLICATED BY GRANULOMA INGUINALE *

LESTER A. WILSON, M.D.
Professor of Obstetrics, Medical College of the State of South Carolina
CHARLESTON, S. C.

Granuloma inguinale is a disease found chiefly in the subtropics, but during the last ten years sporadic cases have been reported from many localities in this country, especially in the South. In Charleston, S. C., it is fairly common; the genito-urinary department of Roper Hospital informs me that it treats about twenty-five cases a year. Kenneth M. Lynch[1] of Charleston and Meredith F. Campbell[2] of New York are to be credited with the most comprehensive study of this condition that has been made in this country. The organisms that are supposed to be the cause of this disease were first described by Donovan in 1905 and are called Donovan bodies.

The method for demonstrating this organism is as follows: A portion of ulceration is selected where the ulceration appears to be spreading, not healing. Wet dressings of physiologic solution of sodium chloride are applied to this area for about twenty-four hours. The surface is then wiped thoroughly with sponges wet with salt solution, and with a dull curet or the edge of a glass micro-slide the surface is deeply scraped. This material is smeared out on several slides and allowed to dry thoroughly. Leishman's stain is applied to the smear, allowed to stand four minutes, then diluted with one half volume of distilled water and allowed to stand one minute. It is washed quickly with running water and dried with a blotter. The Donovan bodies are found scattered through the specimen but more particularly in the endothelial cells having a bluish bacillary or diplococcus appearance surrounded by a pinkish capsular zone.

The disease begins as a small moist papule, which rapidly ulcerates with progressive and eccentric invasion of the surrounding tissues by an elevated, reddish, often shiny, delicately skinned granulomatous proliferation, superficially ulcerating when moist, cracking when dry. Usually, however, the lesions are moist, and a thick mucoid exudation possessing a peculiar odor is characteristic. The disease shows no tendency to spontaneous healing. The genitals and perigenital tissues are most often involved. The disease apparently spreads by auto-inoculation and peripheral extension. Inoculation by transmission from clothing and friction is the probable explanation of its distribution. It is in no sense a venereal disease, as neither the husbands nor any member of the family of these patients give a history of having had granuloma inguinale. The occurrence of elephantiasis of the genitalia or at times of a leg signi-

fies an involvement of the lymph channel. These patients are singularly free from discomfort. An itching or at times a burning sensation plus the presence of the lesion and its accompanying foul discharge constitute the chief complaints. The lesions themselves are but mildly sensitive.

Effect of Granuloma Inguinale on Delivery, Puerperium and Subsequent Health of Mother and Child

Case	Race and Parity	Extent of Lesion and Wassermann Reaction	Delivery	Puerperium	Present Condition
1	Negro; primipara	Ulcerations of perineum and labia; Wassermann negative	Spontaneous; infant normal	Temperature 101 F. for seven days	Mother still under treatment; infant in good health
2	Negro; primipara	Extensive ulcers of perineum and left buttock; Wassermann ++++	Spontaneous; infant normal	Uneventful	Mother recovered; infant in good health
3	Negro; primipara	Ulcerations, symphysis to coccyx 5 in. wide over perineum; Wassermann negative	Spontaneous; infant normal	Temperature 103 F. for two days	Mother's ulcers improved; infant in good health
4	Negro; primipara	Ulcerations of the vulva; Wassermann negative	Premature, 8th month; spontaneous	Uneventful	Mother improved but not entirely recovered; infant died 2 days later
5	Negro; secundipara	Ulcers of the vulva; Wassermann ++++	Spontaneous; macerated fetus	Temperature 101 F. for six days	Mother not improved; claims she delivered a stillborn child 2 years before and had ulcers before that pregnancy
6	Negro; quintipara	Ulcers of the vulva; Wassermann negative	Spontaneous; infant normal	Uneventful	Mother recovered; infant in good health
7	Negro; primipara	Ulcers of the vulva; Wassermann *negative*	Spontaneous; infant normal	Uneventful	Mother recovered; infant in good health
8	Negro; primipara	Ulcers left side of vulva; Wassermann negative	Spontaneous; infant in poor condition	Uneventful	Mother improving; infant died second day, cause undetermined
9	Negro; secundipara	Ulcers and old scar tissue both labia and perineum; Wassermann ++	Spontaneous; lateral episiotomy in old scar tissue; infant normal	Uneventful	Mother recovered; infant in good health
10	Negro; primipara	Ulcers of vulva and elephantiasis left labia, size of grapefruit; Wassermann negative	Not delivered	Mass removed	Patient referred to out patient department for further treatment
11	Negro; quadripara	Ulcers of vulva; Wassermann negative	Not delivered	....	Left hospital against my advice, and am unable to find any further record of her
12	Negro; primipara	Ulcers of vulva; Wassermann negative	Craniotomy; macerated fetus	Pelvic infection, fifteen days' duration	Recovered
13	Negro; tertipara	Ulcers of vulva and perineum; Wassermann negative	Forceps; stillborn infant	Uneventful	Mother improved
14	Negro; quintipara	Ulcers of the vulva; Wassermann *negative*	Spontaneous; infant normal	Temperature 101 F. for seven days	Mother improving; infant in good health

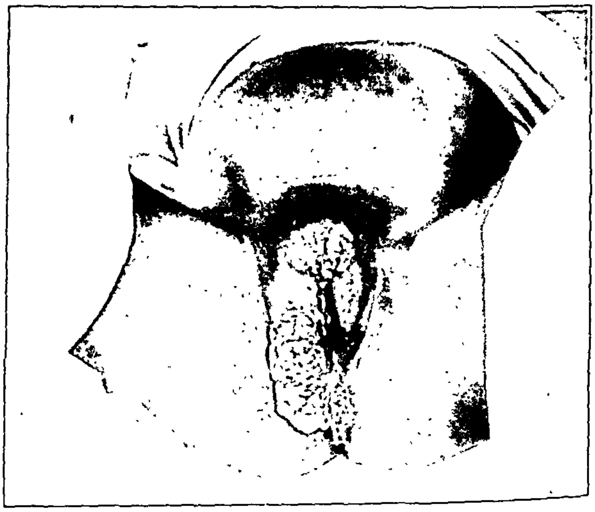
During the last five years I have seen fourteen cases of pregnancy and labor complicated by this condition These patients had typical ulcerations of the vulva or the entire vulvular region, from which exuded a foul, infected discharge that not only bathed the vulva but often extended over the lower part of the abdomen. Confronted with this situation complicating labor, I thought the safest method of delivery was by the natural route, not making either vaginal or rectal examinations. These patients when seen during pregnancy were given the usual treatment of 1 per cent solution of antimony and potassium tartrate intravenously, and local antiseptic dressings. During the puerperium they were kept in an exaggerated Fowler's position.

CONCLUSIONS

1. This series of cases is too small to form the basis for any definite conclusion. However, it seems that there is a tendency to stillbirth and death of infants in granuloma inguinale.

2. Granuloma inguinale is not of venereal transmission, as none of the husbands of these patients were diseased.

3. The Negro race is far more susceptible than the white race.



Appearance of lesions.

4. Under the influence of pregnancy the disease progresses rapidly, probably because of the congestion of the parts; after labor the condition tends to improve.

5. This series of cases shows that the uterus if not traumatized or infected by handling can take care of a great deal of infection.

105 Rutledge Avenue

ABSTRACT OF DISCUSSION

Dr. John P. Gardiner, Toledo, Ohio: Dr. Wilson is to be congratulated on his delivery of a series of fourteen patients having a skin infection such as this and yet having had no greater mortality rate. There was mortality among the children but I doubt whether that is any more than is to be expected under such conditions. As the Negro is migrating north, and as the incidence of this infection is greater in tropical or subtropical people, it behooves men in the North to watch carefully for this disease. In an examination of approximately 5,000 cases, I have never seen a case of granuloma inguinale. Nevertheless, I am on the watch for it. I doubt whether others in the North, and especially in the Middle West, have seen many cases. However, probably in a few years cases of granuloma inguinale will be reported. Granuloma is seen in the neighborhood of the pudenda in its most common forms. This brings up the question of delivery and what to do in generalized cutaneous infection. I had the thrilling experience this spring of delivering one of my patients at the Toledo Contagious Hospital in the active pus stage of smallpox. The vulva was covered with pustules. Fortunately I had observed the patient during the prenatal period. There was no disproportion, so she was allowed to go into labor normally. The infant was vaccinated immediately, the vaccination took, and the mother and child are now doing well. The child did not have smallpox. In these cases of frank infection, as Dr. Wilson brought out, one of necessity refrains from making any vaginal or rectal examination. It taxes at times the ingenuity of the obstetrician to know what method to pursue in cases of frank cutaneous infection. My personal method, if I have not had the opportunity of making an examination except by external palpation, is to induce labor early, if there is any possibility of a disproportion. If there is no disproportion, the patient may be allowed to go into labor and the obstetrician trusts to the immunity of the individual.

Dr. Carey Culbertson, Chicago: This is a condition which is no longer an oriental disease but has appeared in North America. Most of our Negro patients in the Cook County Hospital in Chicago are from the Gulf states and we see more or less granuloma inguinale—one or more cases every year. The condition has been reported in Philadelphia by Dr. McGlinn. A word should be said regarding the differential diagnosis. There are four lesions creating ulceration of the vulva that are somewhat alike. One of them is tuberculosis, which is not seen often but is seen, particularly in the charitable institutions. Another is syphilis—syphilitic ulceration, broken down gumma, or syphiloma of the vulva; it looks like this erosive vulvitis. The third is carcinoma, probably the most frequent, and the other is granuloma inguinale. The treatment of these various conditions is absolutely different, and this is why the differential diagnosis is important. Syphilis is treated by neoarsphenamine. Tuberculosis may be surgical and it may not be. Granuloma inguinale is not a surgical lesion. One of the worst things is to attempt to extirpate it by operation. The result would be a breaking down and an enormous sloughing. It is treated by injections of a solution of antimony and potassium tartrate. It is very chronic and the cure is slow. Carcinoma is treated by surgery or radium. Occasionally, also, an elephantiasis vulvae will break down and become ulcerated. It is another condition that is seen only in colored women. It is best treated by surgery.

Dr. W. E. Tyson, Detroit: I have used metaphen (the anhydride of 4, nitro-5-hydroxy-mercuri-ortho cresol) a great deal in the cure of chancroid. The ordinary chancroid, particularly on the cervix in the female, is a very difficult thing to treat. I have treated quite a number of them unsuccessfully with a local treatment, but I have used metaphen with great success. I have treated several patients who were pregnant. I do not say that there is any relation between the granuloma inguinale and the chancroid, but it just occurred to me whether the metaphen would have any curative effect in this condition as it does in the chancroid. It is most successful with the chancroid. They are much alike.

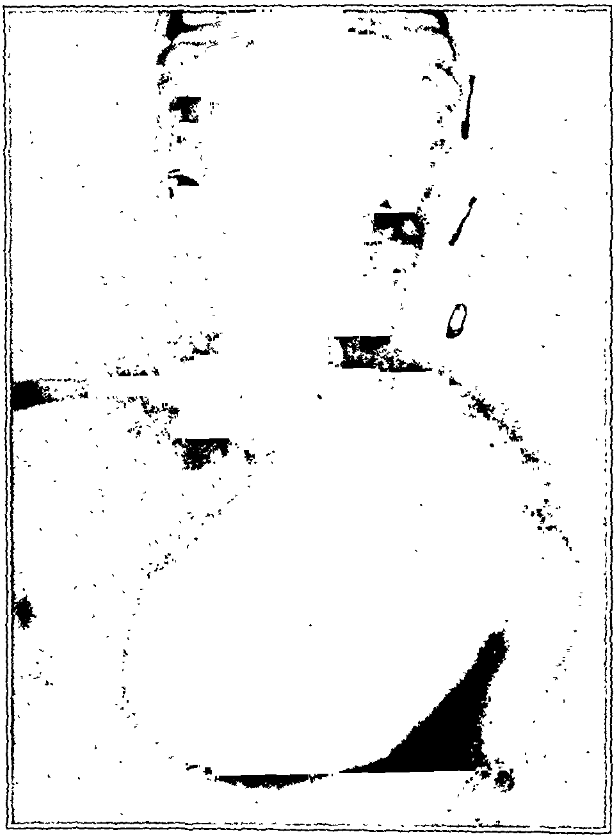
The Diagnostic Clinic at Its Worst.—At its worst, however, the Diagnostic Clinic is a machine, and the patient is automatically passed from one specialist to another and submitted to a series of examinations, so detailed in their nature that it would seem that nothing could be overlooked. The result is a list of so-called "diagnosis"—in reality a list of deviations from the normal, some of which may, and others of which certainly do not have any bearing on the patient's trouble. The unfortunate thing is that only too often the patient undergoes treatment for some of these unimportant conditions and at the same time, because of the lack of some one man who understands the situation as a whole, the real underlying difficulty is entirely overlooked.—Peabody, F. W.: Doctor and Patient, New York, Macmillan Company, 1930.

Clinical Notes, Suggestions and New Instruments

SUCCESSFUL REMOVAL OF A LARGE TERATOMA FROM A NEW-BORN INFANT

Harold A. Rosenbaum, M.D., Chicago

Before the birth of the baby under discussion, the mother was thought by her obstetrician to be carrying a monster. Wisely the obstetrician did a cesarean operation and delivered a baby with a large mass attached to the right perineal and buttock region. This he diagnosed as a meningocele, and a consulting neurologist concurred in the diagnosis. The family was given a hopeless prognosis. When the baby was 18 days old Dr. Louis C. Johnston was called to see her and asked me to see her with him.



Appearance of teratoma.

We found a lusty, crying infant, uncomfortable probably because of the posture necessitated by the large mass mentioned. Her general condition seemed quite normal aside from this mass.

The mass extended entirely from the right side of the perineum and the region of the right buttock. There was so much tension on the anus that there was an almost continual emission of fecal matter. The mass measured 32 cm. in diameter. There was considerable fluid present, but on deep palpation firm bony or cartilaginous tissue could be felt posteriorly toward the coccyx. The skin covering was vascular and bluish.

The knee jerks and the achilles reflex on the right and left were normal, and the thighs, legs and feet were normal. The left buttock fold was normal.

The site and unilateral character of the mass, the normally inervated lower extremities, and the feeling of firm tissue present deep in the mass made us feel that we were not dealing with a meningocele but had to do with a teratoma, and that the baby should be operated on to remove the mass. To exclude the possibility of a loop of intestine coming down into the mass through an imperfect pelvic floor, a series of roentgenograms were taken following a barium meal.

Dr. Johnston operated on the baby, removing the mass, which weighed 2 pounds (1 Kg.) and contained much yellowish fluid. The baby now weighed 7 pounds (3.2 Kg.). The firm tissue which had been felt was diagnosed teratoma on microscopic section. It is interesting to note that almost immediately following the operation the anus began to function normally.

The baby is now 7 months old. She sat alone at 6 months and is in general entirely normal.

4753 Broadway.

AN UNUSUAL CASE OF COMPRESSION MYELITIS WITH POSTERIOR LUXATION OF OCCIPUT[*]

J. Clark Moloney, M.D., and Albert S. Crawford, M.D., Detroit

We report a compression myelitis due to posterior luxation of the occiput. A review of the literature and of the various indexes failed to reveal a parallel case.

History.—A white ex-pugilist, aged 38, came to the clinic, Nov. 23, 1928, complaining of a swollen right knee. It proved to be a neurotrophic joint. A more careful neurologic history elicited the following: When 28 years of age, the patient, as a participant in a prize fight, was struck a terrific blow on the chin; it rendered him unconscious. When he regained his senses, the left side of the body was weak and clumsy and the right leg was numb. The disturbance righted itself in three or four days. He had been "knocked out" about twenty-five times in his career, but never with the same consequences. Ten years later and shortly after the first of the year, 1928, while intoxicated, he fell in a tiled bathroom, striking the back of the neck against the rim of the tub. When he regained consciousness, his left side was again quite useless and clumsy, and the right side numb and "prickly." In four or five days the acute symptoms disappeared. The neck remained stiff. Chiropractic treatments intensified the stiffness and seemed to bring out the original clumsiness on the left and the numbness on the right. Four months later a painless swelling developed in the right knee, and the left side became weaker, slightly spastic and awkward. The right leg could no longer differentiate heat and cold. It was also insensible to pain. Eleven months after the fall in the bathroom, a secondary infection in the swollen right knee brought him to our clinic for treatment.

Table 1.—*Measurements of Right and Left Sides*

	Right, Cm.	Left, Cm.
Mid forearm	27	24.5
Mid biceps	22.5	21
Mid calf	29	27

Examination.—On neurologic examination, there was slight but definite atrophy on the left side (table 1). This atrophy was best demonstrated by the Collins dynamometer; he gripped 125 on the right and from 85 to 90 on the left. The reflexes on the left were pathologically increased and were associated with a left ankle clonus, positive Babinski reflex and presence of the other pathologic toe signs. The left foot slapped the floor as he walked. Occasionally a shudder swept over his frame. On the right, pain sense was lost below the first lumbar segment and thermal sense below the twelfth dorsal segment. Between the right fourth cervical and first lumbar segment a hypesthesia existed. The Babinski reflex on the right was capricious. Tactile discrimination, vibratory sense and joint sense were present and equal on the two sides. The right knee was swollen and anesthetic (fig. 1). Laboratory tests, including Wassermann tests of the blood and spinal fluid, were negative.

Roentgenograms disclosed extensive traumatic arthritis with marked deformity of the mid and the upper cervical vertebrae, but were inconclusive as to cervical dislocation (fig. 2). Combined cisternal and lumbar puncture was done.

---

[*] Read before the Detroit Society of Neurology and Psychiatry, Jan. 9, 1930.

[*] From the division of neuropsychiatry and the division of neurosurgery, Henry Ford Hospital.

Xanthochromia and the syndrome of Froin were absent.

Treatment and Course.—Two cubic centimeters of iodized poppy-seed oil 35 per cent was left in the cistern, and roentgenograms were taken. Most of the iodized oil remained in the cistern (fig. 2). After this procedure, our patient disappeared from the clinic and was not seen again for six weeks. On his return, roentgenograms again revealed a major portion of the iodized oil locked in the cisterna magna.

We diagnosed an upper cervical dislocation or possibly an extradural hemorrhage that had organized. We concluded that either the one or the other was exerting pressure on the left upper anterior aspect of the cord. However, we were totally unprepared for what was subsequently revealed at operation.

One of us (A. S. C.) operated (fig. 3). A high cervical laminectomy was done, exposing the suboccipital region, down to the fifth cervical spine. The spines and laminae of the first four vertebrae were removed. The arch of the atlas was held locked anteriorly by the posterior margin of the foramen magnum. It was removed with great difficulty. When finally removed, the exposed dura was greatly thickened anterior to this arch (4 mm. thick), and when cut through spinal fluid and iodized oil gushed from above. The normal pulsations then began; they were absent before. There was a groove across the upper part of the cord corresponding to the arch of the atlas and the thickened dura. The cord worked backward as soon as the dura was cut through, showing that it had been pressed forward before release. There were adhesions between the arachnoid and the cord and the dura in this region on both sides, which were broken up. A careful search revealed no other pathologic changes. The cord appeared of normal size and consistency. In closing, the upper part of the dura could not be opposed; the defect was covered with animal membranes, and the loose tissues over the area were brought together as well as possible for support. The patient was discharged from the hospital on the twenty-fourth day after operation.

Table 2.—*Results of Punctures*

	Initial Pressure, Mm. of Mercury	Forced Expiration with Glottis Closed		
		Mm. of Mercury	Ascent	Descent
Cisternal puncture..	12	23	Rapid	Rapid
Lumbar puncture...	8	18	Slow	Slow

At first the patient's symptoms and signs were exaggerated. Periodic violent clonic movements of the left leg set in soon after his discharge from the hospital. Change of posture brought about clonic tremors of the head. These disturbances abated when the patient's head and neck were supported by a celluloid collar. Gradually the muscles of the left side regained strength and he was soon able to grip 125 with the dynamometer on the left as well as on the right. The left ankle clonus disappeared. The Babinski capriciousness persisted but to a lessened degree. The arm reflexes became bilaterally equal. The leg reflexes, however, maintained a slight inequality, the left being the more prominent. The right-sided esthesial discrepancies became less and less apparent.

The patient was well on the road toward recovery. However, some five months following operation he went into an acute depression and committed suicide.

COMMENT

Our review of the literature was not enlightening. We unearthed many instances of unilateral dislocation at the same level. However, whether unilateral or bilateral, this type of dissolution of cervical alinement always presented itself between the first and the second cervical vertebrae. In fact, a review of the literature and the various indexes failed to reveal a single case in which the break in alinement manifested itself between the occiput and the first cervical vertebra, with the first and second cervical vertebrae maintaining their normal anatomic arrangement. In this respect, at least, our case is distinctive, for the break in continuity as demonstrated by operation occurred between the occiput and the atlas, the atlas epistropheus relation remaining unaltered. Undoubtedly, dislocation at this particular locale, i. e., between the occiput and the atlas, has happened many times, but, more than likely, always with fatal consequences to the patient. Such instances, presumably, would not find their way into medical literature.

SUMMARY

The sensory changes on the right, the motor changes on the left with bilaterally intact vibratory sensation, represented a definite symptom pattern (fig. 3). This symptom pattern connoted a lesion of the upper cervical cord in the left anterior quadrant. Two cubic centimeters of iodized poppy-seed oil 35 per cent remained in the cisterna for six weeks. Operation revealed a posterior luxation of the occiput on the atlas, or, in other words, an anterior dislocation of the entire spinal column on the occiput. It is reasonable to believe that the posterior arch of the atlas pushed the spinal cord forward, jamming its left anterior aspect against the dens of the epistropheus. The operation released the cord, allowing it to swing backward, removing the pressure from its anterior surface. For five months, barring a short interval directly following operation, the patient made progressive improvement. Then he committed suicide. Review of the literature failed to reveal another case of compression myelitis caused by the posterior dislocation of the occiput.

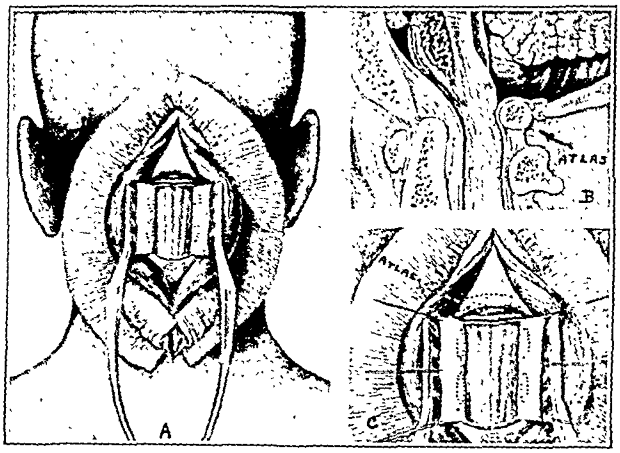

Fig. 3.—All three drawings show the atlas and thickened dura under the margin of the foramen magnum. *B* shows the distortion of the cord.

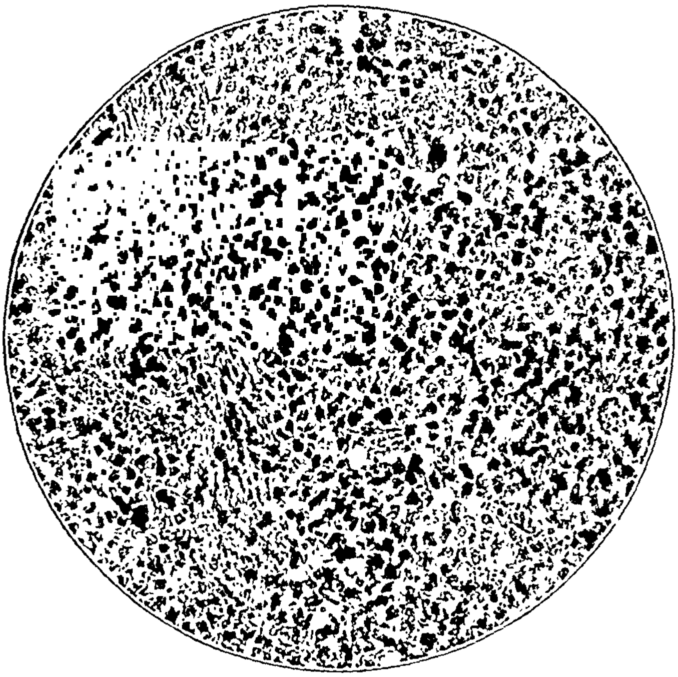
SARCOMA OF OVARY IN A CHILD EIGHT YEARS OLD

Philip Jaisohn, M.D., Reading, Pa.
Pathologist, St. Joseph's Hospital.

Sarcoma of the ovary among children under the age of 10 is quite rare. The available bibliography on the subject in the Surgeon General's Library shows only twenty-four cases between 1888 and 1915, including those reported from Austria, Cuba, France, Great Britain, Germany, Russia, Sweden and the United States. The rarity of the condition warrants my reporting a case that recently came to my observation in this hospital.

Virginia M., aged 8, was admitted to the hospital in the service of Dr. M. Z. Gearhart, Nov. 15, 1929, on the complaint of pain in the lower part of the abdomen and bleeding from the vagina. The physical examination showed that she was quite well nourished and of normal size for her age. There was a mass in the lower part of the left quadrant of the abdomen which was very tender on palpation, and there was some vaginal hemorrhage. This condition was first noticed by her mother about three weeks before her admission to the hospital. Up to that time she had been in excellent health. Since the development of the pain, she had become exceedingly nervous and was unable to rest during the night. The temperature was 101.5 F.; pulse, 120; respiration, 20; blood pressure, 116 systolic and 80 diastolic. The blood count showed 3,670,000 red cells and 9,850 white cells per cubic millimeter of blood, hemoglobin

68 per cent, polymorphonuclears 73 per cent, and small lymphocytes 27 per cent. The urine showed 3 + albumin, occult blood 3 +, and many vaginal epithelium cells but no casts. The roentgenologic observations showed a mass in the left side of the lower part of the abdomen suggesting pelvic origin and the displacement of the colon upward by the mass.



Mixed cell sarcoma of the ovary in a child, aged 8 years, stained with hematoxylin and eosin, slightly reduced from a photomicrograph with a magnification of 450 diameters.

Dr. Gearhart performed the operation of removing the tumor which was found in the left pelvic cavity, involving the ovary and the tube. The tumor was roundish and flat, resembling the shape of a turtle, 15 cm. in length, 8.1 cm. in width, and 6.2 cm. thick, weighing 5.6 Kg. A part of the tumor was necrosed and had undergone a cystic degeneration. The cystlike cavities contained serosanguineous fluid. But the greater portion was fairly firm and well supplied with blood vessels. No trace of the ovary or tube could be seen.

The surface of the tumor was smooth and had no definite capsule except the thin serous covering. On section the tumor tissue presented the white glistening texture which is usually found in the sarcoma of mesenchymal origin. Under the microscope the solid portion of the tumor showed several varieties of cells—round cells, spindle cells, large spheroidal cells and a few giant cells. The stroma was rather scanty and the lumen of the vessels were well crowded with the atypical cells. The accompanying photomicrograph of a section of the tumor well illustrates the major portion of the growth.

There was apparently no involvement of other pelvic organs, nor was there any indication of metastasis in the remote part. The child made a rapid recovery from the effect of the operation and was discharged in two weeks. Up to this writing, more than six months after the operation, she is in good health and has gained 10 pounds (4.5 Kg.) in body weight.

For the want of a better term, I called the tumor a mixed cell sarcoma, but as to its exact histogenesis I am uncertain. The ovarian stroma might have been the seat of its origin, or possibly it might have sprung from some aberrant cells of teratomatous nature. At any rate a guarded prognosis was given, although the postoperative condition of the patient is quite favorable so far.

BRONCHIOGENIC CARCINOMA WITH CEREBRAL METASTASIS IN A PATIENT WITH KYPHOSIS*

MITCHELL BERNSTEIN, M.D., PHILADELPHIA

The diagnosis of intrathoracic cancer in a patient with a deformed chest obviously offers many difficulties. This is especially true in a patient with thoracic deformity when the subjective symptoms suggest the diagnosis of pulmonary tuberculosis with atypical signs. In addition, the pathologic involvement of several cranial nerves further complicates the clinical picture. However, the diagnosis of possible pulmonary cancer with cerebral metastasis, as occurred in the case herein reported, should not be overlooked.

REPORT OF CASE

History.—E. C., a man, aged 48, was admitted to the service of Dr. Bernard Kohn at the Jewish Hospital, Jan. 29, 1930, because of a chronic productive cough together with weakness, night sweats, slight fever and headache. These symptoms had existed for about four weeks prior to admission.

During infancy the patient sustained an injury to the upper spine, the exact nature of which was unknown. This injury supposedly resulted in the permanent deformity of his vertebral column. At 33 years the patient had pleurisy on the left side. About this time he developed a chronic productive cough which had persisted and which became aggravated one month prior to admission to the hospital. There was no hemoptysis. The patient had never suffered with headaches previous to one month before admission, when they made their appearance and were almost constant. Concomitant with the headache, appeared night sweats.

At the time of admission the patient developed double vision. Slight fever was present, the temperature ranging from subnormal to 100.8 F.

Physical Examination.—On admission to the hospital the patient was pale and appeared quite ill. There was a palsy of the left external rectus muscle and a slight weakness of the right side of the face. There was a loss of function of the left masseter muscle. These observations were indicative of the involvement of the left fifth, left sixth and right seventh cranial nerves. Otherwise, the cranial nerves were apparently normal. The eyegrounds did not present any changes.

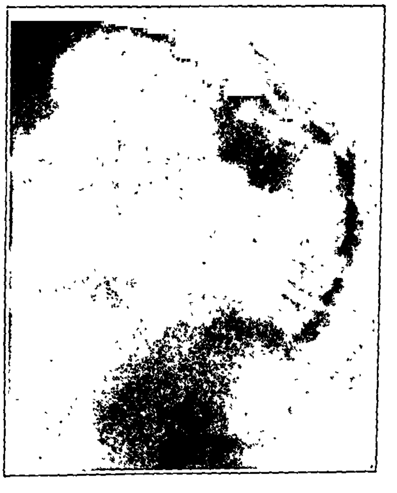


Fig. 1.—Lateral view of the chest showing the marked kyphosis and the malignant mass.

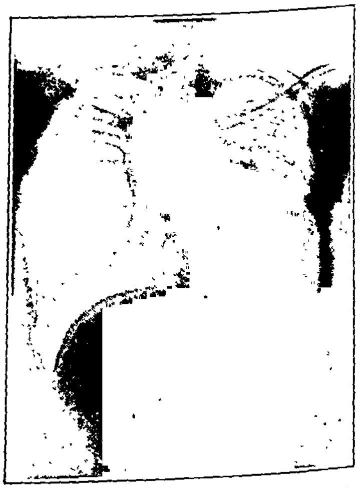

Fig. 2.—Dorsal view showing the kyphosis and the malignant mass in the left lung.

The patient's chest was deformed by the presence of a marked thoracic kyphoscoliosis. Because of this deformity it was difficult to outline the heart. On percussion, the apex of the right lung was found to be impaired, both anteriorly and posteriorly. The breath sounds here were quite harsh. Vocal fremitus and pectoriloquy were increased. On the left side posteriorly there was an area of dulness, close to the kyphoscoliotic curve and extending between the fifth and eighth ribs, to the inner border of the left scapula. Over this area the breath sounds were suppressed and at some points they were entirely absent. Vocal fremitus was diminished. Below this area the lung was hyperresonant; the breath sounds were exaggerated and vesicular in type, and showers of moist râles were heard from time to time.

---

* From the Medical Service of Dr. Bernard Kohn, Jewish Hospital.

The abdomen was essentially normal. The reflexes of the extremities together with the superficial abdominal reflexes were normal.

Examination of the blood showed the hemoglobin content to be 76 per cent, red blood cells 4,300,000, white blood cells 6,500, 64 per cent polymorphonuclears, 36 per cent lymphocytes. On chemical analysis the blood was normal. The blood Wassermann test was negative. The spinal fluid was removed under normal pressure, showed no chemical or microscopic abnormalities, and yielded a negative Wassermann test.

Repeated examinations of the sputum were negative for tubercle bacilli.

The feces showed no parasites or occult blood. Several examinations of the urine showed traces of albumin and occasional hyaline casts as the only abnormalities. The phenolsulphonphthalein and Mosenthal tests were normal. The gastric analysis showed a normal gastric curve.

A roentgen examination of the chest (figs. 1 and 2) was made by Dr. Sidney Feldstein, who reported that the heart shadow appeared about normal in size. Its situation was not clearly defined on account of the spinal deformity. Both domes of the diaphragm were clear. The interspaces on the right side were much farther apart than on the left, also on account of the spinal deformity, and the lung structure itself showed no abnormality. On the left side the interspaces were so close together as almost to produce contact of one rib with the other in the upper half of the chest. In the region of the root there was a distinct area of increased density. The upper lobe appeared perfectly nomal. The dorsal spine showed a marked curvature posteriorly, the upper dorsal to the right and the lower dorsal to the left.

Course.—February 3, vomiting occurred and lasted for three days. The headache which was present on admission became quite severe and annoying. The double vision persisted.

February 15, the headache became unbearable and was localized to the supra-orbital region.

March 3, following a period of acute delirium which lasted about one hour, the patient died.

Necropsy.—The essential features of the necropsy observations reported by Dr. B. A. Gouley were as follows: The trachea and lungs were removed *en masse*. There was a large intrapulmonary mass in the root of the left lung, the lesion extending out along the left main bronchus. This mass was irregular but its main portion measured about 3 by 3½ inches. The pleurae were smooth. There was an enlarged node about 1½ inches in diameter, hard and firm at the hilus of the right lung. Dissection of the trachea and the left bronchial tree revealed a bronchiogenic cancer that extended half way to the periphery of the lung and to a lesser degree toward the base. There was marked narrowing of the bronchial lumen because of the bronchiogenic hyperplasia. A purulent exudate was found over this area, extending into smaller bronchial branches. The lower lobe presented an atelectasis, some of which was undoubtedly due to the bronchial obstruction, the other possible factor being the kyphoscoliosis. The rest of the left lung, that is, the upper lobe, was emphysematous. The bronchial tree to the involved portions presented a generalized dilatation and was coated by tenacious catarrhal exudate. The right lung was large and markedly emphysematous. The bronchial tree here was uniformly dilated and similarly coated by tenacious mucus. The bronchial branches could be dissected to the extreme periphery. The appearance was that of asthma and resultant emphysema. The enlarged right bronchial lymph node presented on section firm white homogeneous tissue similar to that of the left bronchial cancer. Metastatic lesions were found at the hilus of the suprarenal. Lymph nodes found at the beginning of the common bile duct were moderately enlarged and firm and were probably the seat of early metastatic involvement.

The body and tail of the pancreas contained hard white nodules from one-half to one inch in diameter, fairly well circumscribed, presenting definite secondary characteristics. The gastro-intestinal tract showed no organic lesion.

The brain was removed and was found to be of normal size. There was no evidence of meningitis, either acute or chronic. There was a soft tumor in the pituitary area extending to the left of the midline pressing on the sixth nerve and involving the roof and the lateral wall of the left sphenoid sinus. The roof was easily broken through; the sinus appeared to be noninvolved but its lateral wall had broken down.

The essential features of the histologic report are as follows: Section of the pancreas and peripancreatic lymph node showed the presence of malignant cellular hyperplasia. The growth was made up of large round and polyhedral cells with hyperchromatic nuclei. These cells were closely packed, forming large alveolar clumps. Other areas showed the cells to be arranged in continual rows and layers. There was scanty but definite stroma formation along which these layers and alveolar clumps were arranged.

Section of the lung showed little or no part of the original lung structure. There was a diffuse fibrous proliferation in the crevices, presenting a rich growth of malignant epithelium with hyperchromatic nuclei and the cells arranged in layers of solid alveolar clumps. They were the columnar type of epithelium. The transition from the normal was not seen in this section. Another lung section showed diffuse neoplastic growth to the exclusion of all but a small piece of the original lung structure. Here was found a small distorted bronchiole, lined by a single layer of cuboidal, or even flat, epithelium. This was part of the transition process, although direct outgrowth from this point could not be seen. It was probably created from similar bronchioles showing this metaplasia.

On examination of the brain, section of the dura showed an invasion of the neoplastic tissue similar to that described in the lungs and the peripancreatic lymph node. Curiously, the new growth was confined in large thin walled spaces in which red blood cells were noted and surrounding small blood vessels that were present already. The malignant condition was denoted by their atheromatous thickening.

The cerebral lesion apparently was confined to the dura region of the infundibulum and caused compression against the pituitary body.

COMMENT

Although cases of bronchiogenic carcinoma are not uncommon, the occurrence of this disease in a patient with a deformed chest may be overlooked, or the diagnosis of pulmonary tuberculosis may be made erroneously. In addition, the involvement of the several cranial nerves, together with vomiting and headache, would suggest the diagnosis of brain tumor.

In our patient the vomiting and headache together with the involvement of the cranial nerves pointed to an intracranial complication. Of course, this may have been tuberculous. However, normal reflexes and the negative spinal fluid, together with a lesion in the left chest at an area not usually affected alone by tuberculosis, served to make the diagnosis of cancer practically certain.

In this connection it may be well to recollect that Fried and Buckley[1] have recently called attention to the fact that bronchiogenic cancer frequently metastasizes to the central nervous system. In reality, this metastasis occurs so frequently that in eleven of fifteen such cases collected by them the bronchiogenic tumor was overlooked, and the clinical diagnosis of primary brain tumor was made.

CONCLUSION

The presence of a marked kyphosis or kyphoscoliosis in any patient with pulmonary disease, during the age when carcinoma is most common, should not mislead us from keeping in mind the possibility of intrathoracic cancer. Moreover, when a patient of this type shows intracranial symptoms in addition to the thoracic signs a critical survey for primary carcinoma should be made.

AIR CONDITIONING FOR PREMATURE INFANTS

The adaptability of the human organism to marked variations in its external environment—changes in temperature, humidity, movements of the air and isolation—is so well perfected under the usual conditions of living that one rarely stops to consider the limitations that are sometimes imposed on such adjustments. The adult supplements his innate capacity to survive in unfavorable surroundings by means of suitable clothing, together with artificial heat or cooling devices, as the circumstances may demand for his physiologic welfare or personal comfort. Furthermore, he has learned in recent years from hygienic studies that some of the once feared and supposedly noxious factors that may insidiously threaten him are after all of negligible significance. This observation refers particularly to the product of his own respiratory functions—carbon dioxide—to variations in the oxygen content of the inspired air, and to the vague toxic components supposed to vitiate the air that has been breathed by living beings.

Scientific investigation has discovered either that these dreaded menaces are nonexistent, as in the case of the "respiratory poison," or that they are of little significance under the ordinary conditions of life in relation to adult man. The latter can endure relatively high concentrations of carbon dioxide without deleterious effect or any consequences other than an augmented rate of respiration. Shortage of oxygen ordinarily occurs only at high altitudes or in such exceptional situations as may be presented by submarine disasters. Man has thus learned that his welfare and particularly his sense of well being depend, so far as the environmental influences are involved, largely on the ability to preserve the normal function of his heat-regulating mechanism. The latter represents one of the marvelous devices of man's physiologic equipment.

The preservation of a fairly uniform body temperature, representing a remarkable adjustment between heat production and heat loss in the midst of changing atmosphere and metabolism may be annulled by disease. It is admittedly imperfect during the early days of life. The infant not only is helpless with respect to the adjustments represented by variations in clothing, but also only gradually develops to better efficiency the physiologic mechanism designated as temperature control. Even more helpless and maladjusted are the prematurely born infants coming into the world between the sixth and the ninth month of fetal life—puny prospects weighing between 1½ and 5½ pounds. Most unfortunate are the congenitally diseased or sick premature infants suffering from congenital anomalies, birth injuries and acute or chronic infections.

A recent writer has defined success in the treatment of premature infants as depending mainly on four factors: stabilization of body temperature, proper nutrition, nursing care, and prophylaxis against infection. The management of body temperature has until comparatively recently depended on special heating devices such as hot pads, heated beds and electrical incubators. Of late, however, plenum systems of heating and ventilation have received consideration and begun to obtain some vogue.[1] A group of investigators[2] at the Harvard School of Public Health and the Harvard University Medical School in Boston have pointed out that, although the importance of air temperature has been generally appreciated, the direct effects of humidity and rate of air change on body temperature, with their indirect effects on nutrition, growth, infection and the like, have not been fully understood. Doubtless part of this criticism would apply in some measure to conditions of adult living also. Most of the methods now in use, we are told further, have failed to fulfil the environmental needs of premature infants on account of limited air space, inadequate ventilation, insufficient humidification in winter, and lack of facilities for cooling and dehumidifying the air in warm weather. The authors assert that when mechanical ventilation is used there has been a tendency to fix the temperature of a single room at 80 F., regardless of the humidity and of the individual requirements of the infants.

The problem of proper air conditioning is one for the engineer rather than the physician. The latter must, however, establish the physiologic requirements that the apparatus shall meet. The comfort zone and effective temperature index determined for adults[3] cannot be applied without reserve to infants who still have aberrant metabolic and circulatory functions as well as incomplete development of their sweat glands. From observations on body temperature, gain in weight, incidence of diarrhea, mortality, and general behavior of premature infants under various humidity conditions, the Boston investigators[2] adopted a relative humidity of 65 per cent as most satisfactory. Low humidities, such as prevail in many nurseries during cold weather, tended to promote instability of body temperature and other untoward symptoms. The temperature requirements for normal premature infants varied from 75 to 88 F. With the congenitally diseased infants the desirable temperatures of environment showed even greater ranges. Temperatures as high as 100 F. are sometimes temporarily employed. These are attained by the use of individual electrical incubators placed with tops open inside the larger nursery. In this way the infants breathe the comparatively cool room air at about 65 per cent humidity, and the persons in attendance are not subjected to extreme temperature conditions. At the Infants' Hospital in Boston a ventilation rate of twenty-five air changes an hour and an air movement of 15 feet a minute in the nurseries for premature infants have been found advantageous. The application of air conditioning has been followed by marked reduction in the incidence of diarrhea and the mortality rate. Infections were reduced and gains in body weight increased. These are statistical facts. The benefits must be attributed, however, to advances in medical treatment and improvement in nursing and general care, as well as to the installation of a carefully planned air conditioning system.

THE CEREALS IN NUTRITION

The cereal grains are the backbone of the nutrition of most of the races of the earth. They are, as a rule, the cheapest sources of food fuel; so that corn, wheat, rice, rye, barley and oat kernels are to be found constituting a third or often much more of the calory intake of the millions of persons involved. Some of these cereal products are used in almost the same form as that in which they are supplied by nature.. They may be ground or pulverized and cooked, but not otherwise greatly altered. On the other hand, a few of the cereal seeds are manipulated or milled so that a part of the natural kernel is discarded. This is notably true of rice and wheat; in lesser degree also of corn. Aside from these alterations, however, there is a running debate as to the relative nutritive values and physiologic properties of the various cereals. From the chemist's standpoint there is little occasion to attribute any especial superiority to one of the common cereal grains over its usual competitors. All are abundant in starch, have a modicum of protein that does not quite match most animal proteins in biologic value, include essentially the same content of a few inorganic ingredients, and have a complement of vitamins that is not conspicuous or diversified. Despite this, one may observe the dispute of relative virtues entering from time to time into the propaganda for trade preference.

A recent issue of the *Journal of Nutrition* contains a number of contributions[1] that may serve to dispel misgivings regarding any great differences among the commonly eaten whole grain cereals. Mattill has substantiated earlier investigations in showing how small are the differences between the oat and wheat under comparable feeding tests. The oat protein apparently possesses a slight advantage over the wheat protein, and the presence of a small amount of bran in the latter does not alter its biologic value. In terms of comparative figures, the data are 89 for milk, 82 for oats and 73 for wheat preparations.

In studies of the gastric response to different cereal breakfast foods, Clough, Carman and Austin observed only slight differences in the rates of evacuation of the stomach when different products formed the test meal in the same person. The foods were cooked in a uniform manner and eaten with the same amount of sugar and cream in each instance. On the average, wheat endosperm and whole oats showed 83 per cent and 76 per cent, respectively, evacuation at the end of the same periods of observation. Roughage in the form of bran in normal proportions or less appeared to influence evacuation time of the stomach but little in any way.

Current Comment

THE SO-CALLED HEART HORMONE

The demonstration that a few tissues of the body yield chemical substances that are physiologically potent in small quantities has led to the search for "active principles" in many organs. Secretin, insulin and epinephrine are significant illustrations of the accomplishments of the past. The quest of hormones has become the ruling passion as well as the scientific pastime of many investigators. One reads of alleged discoveries of a kidney hormone, an intestinal hormone, and even of a heart hormone. The latter has been postulated as a constituent of extracts of the heart tissue having a characteristic stimulating action on the organ itself. The possibility of producing such effects is admitted; but that there is anything specific in cardiac tissue extracts has been repeatedly denied.[2] An explanation for the known phenomena seems to be afforded by Thorpe's isolation of histamine from the heart.[3] Extracts of the ventricles show a powerful depressor activity that is readily explained by the presence of the amino-acid derivative. In view of the relatively large amounts of histamine both in auricular and in ventricular tissue, it seems probable to Thorpe that the reputed cardiac stimulating effect of heart extracts may be due wholly or at least in large part to that substance. Other tissues also yield histamine; it therefore cannot be a specific heart hormone.

THE SUGAR IN PENTOSURIA

The nature of the carbohydrate in the urine in ordinary cases of glycosuria has long been established as dextrose. It has the familiar and characteristic properties of reducing alkaline copper solutions, rotating the plane of polarized light, and undergoing alcoholic fermentation with yeast. For decades, physicians have been in the habit of testing urine with Fehling's solution or one of its more modern substitutes; and the reduction produced in it by sugar-containing urine has served as a diagnostic index. Dextrose is, however, not the only substance appearing in urine that reduces Fehling's solution. Nearly forty years ago Salkowski and Jastrowitz[1] of Berlin described the first recognized case of pentosuria in man. The origin of the five-carbon sugar in human metabolism still remains obscure, as does the precise chemical structure of the particular pentose that is excreted in an anomalous manner. There have been reports that the sugar is a form of arabinose, $C_5H_{10}O_5$; but the most convincing identifications pointed to *d*-xyloketose as the unique carbohydrate present in the urine of pentosuria. This has now been substantiated for four additional patients by Greenwald[2] of New York University. The establishment of the usual, if not the invariable, structure of the sugar will pave the way toward a better interpretation of the biochemical significance of an "inborn error of metabolism."

THE BACTERIA RESPONSIBLE FOR UTERINE SEPSIS

Not every case of fever in the puerperium is attributable to genital sepsis. The first step in incriminating specific bacteria in cases of puerperal morbidity is to discover by careful clinical examination as well as by the bacteriologic examination of the uterine contents which cases may be properly classified as uterine sepsis. Using both these methods in a study of 125 febrile cases, Taylor and Wright[3] have found in 50 cases certainly and in 27 others probably that fever was due to an extra-uterine cause. In 48 cases there was definite uterine sepsis. Of these, 14 were caused by hemolytic streptococci, 10 by anaerobic cocci and eight were mixed infections with *B. coli* predominating. Only two of the cases ended in death, and each of these patients was infected with type I pneumococci. Not all of these patients had been examined before delivery, but of the 21 who had been so examined only 4 harbored the causative organism in the vagina at the time of examination. The writers therefore concluded that bacteria present in the vagina before delivery are apparently a less serious danger than those which enter during or after labor. They lay emphasis on the frequency with which they have found anaerobic cocci in septic uteri, a finding in accordance with the previous work of Harris and Brown at Johns Hopkins.[4] The prognosis of genital infection cannot be made from a bacteriologic study of the flora. Prognosis and diagnosis, here as elsewhere, are essentially a clinical problem. The bacteriologist may, however, render valuable service in tracing the origin of exogenous infection. It was proved, for example, in the study of Taylor and Wright that one of the fatal infections with type I pneumococci was derived from the nose of an attendant. More definite knowledge is needed as to the chief sources of dangerous exogenous infection during the puerperium, and bacteriologic research must provide the next advance in this direction.

LIPOID HISTIOCYTOSIS

The histiocytes are large phagocytic interstitial cells forming a part of the reticulo-endothelial system. In lipoid histiocytosis, or Niemann's disease, the histiocytes undergo a change; they become filled with cholesterol fat which gives them a foamy appearance; hence the name foam cells. In lipoid histiocytosis, masses of foam cells may lie free in the alveoli of the lungs and may be packed in the pulp of the spleen and the sinusoids of the liver; they almost completely replace the marrow cells in the bones and fill the sinuses in the lymph nodes. The principal microscopic feature of lipoid histiocytosis is the presence of great numbers of vacuolated foam cells in the spleen, liver, lymph nodes, bone marrow, lungs, suprarenal, thymus and lymphoid structures of the intestine and the central nervous system. Clinically, lipoid histiocytosis is characterized by progressive emaciation, enlargement of the spleen and liver, and death before the patient is 2 years of age. The patients are usually physically and mentally retarded; brownish pigmentation of the skin may be present, with slight enlargement of the lymph nodes, a moderate leukocytosis and a slight progressive anemia. The historical background of lipoid histiocytosis is related by Baty,[1] who has placed on record the sixteenth case of this recently discovered clinical entity. In 1914, Niemann reported a case of Gaucher's disease in an infant. Knox, Wahl and Schmeisser reported later two similar cases in infant sisters; Siegmund reported the fourth case in an infant. In studying this group of four cases, Pick brought out the fact that they had peculiar characteristics in common: the age of onset, the clinical course, the distribution of the foam cells in the viscera, and the racial tendency. He clearly established this condition as a clinical entity entirely distinct from Gaucher's disease. Bloom reported three more cases and proposed the name "lipoid histiocytosis" to designate a condition which involved the storage of lipoid material in the histiocytes throughout the body. Single cases have been reported since, until the total has reached sixteen. It may be significant that eight of them have been reported in the last three years. The cause of this rare disease of infants is unknown. There is no evidence of developmental anomalies to explain the symptoms. The failure to store fat in the normal depots may be an indication of a profound metabolic distur-

bance, and the entire symptomatology may be only the secondary effect of that disturbance. In his report, Baty interestingly speculates as to whether or not this is a new affliction of man, possibly brought about by the change of diet coincident with the advance of civilization. It seems that a condition with pathologic changes so striking would have been recognized before, if it had been in existence.

Association News

ABSTRACT OF MINUTES OF MEETING OF BOARD OF TRUSTEES HELD IN CHICAGO, SEPT. 25 AND 26, 1930

The Board of Trustees met in Chicago on Thursday and Friday, Sept. 25 and 26, 1930.

COMMITTEE TO STUDY PROBLEMS OF MENTAL HYGIENE AND HOSPITALS

To meet the instructions from the House of Delegates, the Board appointed the following Committee to Study Problems of Mental Hygiene and Hospitals: Drs. H. Douglas Singer (chairman), Chicago; Walter L. Treadway, Washington, D. C.; J. Allen Jackson, Danville, Pa.; F. G. Ebaugh, Denver, and E. J. Emerick, Columbus.

PUBLIC HEALTH CONFERENCE POSTPONED

Because of the inability of a large number of state health officers to attend the conference on public health this year, it was decided to postpone the proposed conference until 1931.

REPLICA OF EX-PRESIDENTS' MEDAL TO BE PLACED IN THE MUSEUM OF THE CLEVELAND MEDICAL LIBRARY ASSOCIATION

In response to a request from the curator, a replica of the medal presented to ex-presidents of the Association at the Detroit session will be placed in the museum of the Cleveland Medical Library Association.

DR. LOUIS CASAMAJOR ELECTED TO EDITORIAL BOARD OF ARCHIVES OF NEUROLOGY AND PSYCHIATRY

Dr. Louis Casamajor of New York was elected a member of the editorial board of the *Archives of Neurology and Psychiatry* to succeed Dr. Samuel T. Orton, who tendered his resignation because of press of other duties.

COMMITTEE ON ENTERTAINMENT AT ANNUAL SESSIONS

Drs. Austin Hayden and F. C. Warnshuis were appointed a Committee on Entertainment at Annual Sessions, with power to add to the committee a sufficient number to carry out the plans of the Board of Trustees.

COMMITTEE ON LEGISLATIVE ACTIVITIES

As requested by the House of Delegates, the Board of Trustees appointed a committee on legislative activities, the personnel of which is: Drs. J. H. J. Upham, Columbus, Ohio; Thomas Cullen, Baltimore; D. Chester Brown, Danbury, Conn.; C. B. Wright, Minneapolis, and E. H. Cary, Dallas, Texas.

FOREIGN BODIES IN RESPIRATORY PASSAGES IN CHILDREN

The resolution of Dr. J. D. Brook of Michigan, which was presented to the House of Delegates, concerning foreign bodies in respiratory passages in children was referred to the Bureau of Health and Public Instruction, with the request that that body take the matter up with the manufacturers of children's toys.

REPORT OF COMMITTEE ON SCIENTIFIC EXHIBIT

The report of the Committee on Scientific Exhibit was approved. Dr. Ralph H. Major and Dr. Hans Zinsser were elected to succeed themselves as members of the Advisory Committee, and the incoming chairman of the Council on Scientific Assembly, Dr. John E. Lane, was elected an ex-officio member of the committee.

COMMITTEE ON MOTION PICTURE AND TALKING FILM IN MEDICINE

In response to the request of the House of Delegates, Dr. Carl H. Davis of Milwaukee and Dr. C. P. Emerson of Indianapolis were appointed a Committee on Motion Picture and Talking Film in Medicine. A third member will be selected.

RESOLUTION FROM MINNESOTA STATE MEDICAL ASSOCIATION PERTAINING TO TRAINING OF RESERVE OFFICERS

The resolution adopted by the House of Delegates of the Minnesota State Medical Association, proposing that changes in the army regulations concerning reserve officers should be made to provide for recommission and reassignment of chiefs and assistant chiefs of professional services of hospital units, even though they have not completed the required amount of military work, having been reported on by the Committee on Military Affairs and National Defense, was not approved by the Board of Trustees.

BUREAU OF MEDICAL ECONOMICS

The organization of a Bureau of Medical Economics is in progress and will receive further consideration at the next meeting of the Board of Trustees.

LEAVE OF ABSENCE FOR DR. NATHAN P. COLWELL

A leave of absence to the first of the year 1931 was granted for Dr. Nathan P. Colwell, secretary of the Council on Medical Education and Hospitals.

DATE OF PHILADELPHIA SESSION OF THE ASSOCIATION

The week of May 11 was decided on for the next annual session of the Association, to be held in Philadelphia, in 1931.

MISCELLANEOUS BUSINESS

Many other matters of importance were considered; some were referred to various councils and bureaus; action on others was deferred until a later meeting.

THE PHILADELPHIA SESSION

Application Blanks for the Scientific Exhibit

Circular letters containing the information on the Scientific Exhibit for the 1931 session, together with the application blanks, will be mailed about the middle of November. Any who desire to receive the circular letter and application blank should mail a request to the Director, Scientific Exhibit, American Medical Association, 535 North Dearborn Street, Chicago. The Committee on Scientific Exhibit requires that all applications for space must be made on the regular application form.

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Talks

The American Medical Association broadcasts at 10 a. m. on Monday, Tuesday and Saturday, over Station WBBM (770 kilocycles, or 389.4 meters).

The program for the week is as follows:

October 13.	If I Were Mussolini.
October 14.	Drink to Your Health.
October 18.	The Work of a City Health Department.

Five minute health talks may be heard over the Columbia Broadcasting System daily except Sundays and holidays, from 12 to 12:05 p. m.

The program for the week is as follows:

October 13.	Accidents Can Be Prevented.
October 14.	Concerning Cancer.
October 15.	The Carbon Monoxide Monster.
October 16.	The Likelihood of Longevity.
October 17.	Crashing the Health Gate.
October 18.	Exceptional Exercise.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest: such as relate to society activities, new hospitals, education, public health, etc.)

ARKANSAS

Society News.—The annual state health conference, September 11-12, was addressed, among others, by Drs. Jesse D. Riley, State Sanatorium, on the care and treatment of tuberculous patients, and Frank Vinsonhaler, dean, University of Arkansas School of Medicine, Little Rock, "Rôle of the Medical School in Preventive Medicine."——The Craighead-Poinsett County Medical Society was addressed, August 7, by Dr. Homer A. Stroud, Jonesboro, on tularemia.——The Jefferson County Medical Society was addressed, September 2, by Dr. Joseph F. Gill, Pine Bluff, on typhoid.——The Tri-County Medical Society (Union, Ouachita and Columbia counties) was addressed, September 4, at Camden by Drs. Rufus B. Robins, Jr., Camden, on "Cardiolysis"; Morris S. LeDoux, Shreveport, La., "Modern Treatment of Syphilis"; Robert G. Douglas, Shreveport, La., "Diseases of the Colon," and Jesse D. Riley, State Sanatorium, tuberculosis.

CALIFORNIA

Society News.—The Butte County Medical Society was addressed at Oroville in September by Drs. Francis H. Redewill on "Modern Therapeutic Treatment in Urology," and James E. Potter on "Treatment of Tertiary Syphilis." Both speakers were from San Francisco.

Diphtheria Decreases.—The San Diego City Health Department reports that no deaths from diphtheria occurred between January 1 and September 10. Only twenty cases were reported during this period. During the year there were twenty-three out of thirty-six weeks in which no cases were reported, and eleven consecutive weeks with no cases. Immunization against diphtheria, which was inaugurated in 1926, has proceeded continuously. An intensive campaign has been carried on this year. The cases have dropped from 251 in 1926 to 85 in 1929.

Changes Among Health Officers.—Dr. Herbert F. True became city health officer of Sacramento, September 15, succeeding Dr. James R. Snyder, city bacteriologist, who had been acting health officer since the resignation of Dr. John Howard Hall. Dr. Roy E. Allen is now city health officer of Reedley, succeeding Dr. John D. Hare. Dr. Paul G. Capps has been appointed health officer of Contra Costa County to succeed Dr. Ira O. Church, who has been granted a leave of absence of one year to take postgraduate work at the Johns Hopkins University School of Public Health at Baltimore.

GEORGIA

Personal.—Dr. James L. Bevans has resigned as director of the John D. Archbold Memorial Hospital, Thomasville, with which he has been connected for seven years, coming as its first superintendent. His successor has not been appointed. Dr. Bevan's resignation will become effective, February 1.

ILLINOIS

Restoration and Revocation of Licenses.—The department of registration and education announced the restoration, September 4, of the medical license of Dr. Louis H. Hayes, Alton, which was revoked, June 3, 1927, on the grounds of conviction for violation of the Harrison Narcotic Act. The license of Dr. Ernest Richard Neubert, Marshall, was revoked, September 11, on the grounds of conviction of violation of the Harrison Narcotic Act. The license of Dr. George E. Fosberg, Chicago, was revoked, August 21.

Prevention of Trachoma.—At a series of clinics sponsored by the U. S. Public Health Service, the Illinois Society for the Prevention of Blindness and the state department of public health recently, 125 cases of trachoma were discovered in southern Illinois. About 600 people among relatives or close contacts of blind pensioners were examined. The state department of health has recently appointed a full-time nurse who will promote the care of patients. Her duty will be to follow up all cases with the idea of getting them under competent medical care.

Society News.—The conference of Illinois Health Officers and the Illinois Municipal League will be held, October 16-17, at Springfield. Among the speakers will be Drs. Allan J. McLaughlin, U. S. Public Health Service, on "Trends in Public Health Service"; Joseph W. Mountin, director, rural health service, Tennessee State Health Department, "The Legitimate Field of the Health Officer"; Don M. Griswold, deputy health commissioner of Michigan, "Diphtheria Control Outlook"; Gilbert Fitzpatrick, "Cancer and the Public Health"; Clarence W. Hopkins, Chicago, "The Experience of a Railroad with Preventive Medicine," and Siegfried Maurer, Chicago, "Program for Saving the Infant Under One Week Old." The luncheon for health officers will be addressed by Dr. William F. King, state health commissioner of Indiana, on "Economics of Public Health Work."——Dr. Robert J. Crossen, St. Louis, talked on "New Aspects of Uterine Bleeding" before the St. Clair County Medical Society, East St. Louis, October 2.

Chicago

Personal.—Lord Berkeley Moynihan was recently guest of honor at the Murphy Memorial Building, where he had given the initial Murphy Memorial Lecture.

Founders' Day Celebrated at Northwestern.—The seventy-second anniversary of the celebration of the founding of Northwestern University Medical School was observed on McKinlock Campus, September 30. The principal speaker was Dr. Isaac A. Abt, who reviewed medical history of recent years as related to medical education in America.

Oxygen Rooms for Treatment of Pneumonia.—Two oxygen rooms for the treatment of patients with pneumonia were recently opened at the Michael Reese Hospital. The rooms constructed at a cost of $10,000, are made of regular building materials instead of special materials used in some other oxygen rooms. The room can be charged with the maximum of oxygen needed in from three to five minutes. One door is large enough so that the patient can be rolled into the room on a bed. The door then is closed and a small door which leads into an airlock is used for the entrance and exit of nurses and physicians.

Society News.—The Chicago Society of Industrial Medicine and Surgery was addressed, October 1, by Dr. John A. Wolfer on "Lesions of Abdominal Viscera Encountered by the Industrial Surgeon." A motion picture film on traumatic surgery of the extremities was shown.——The second annual Arthur Dean Bevan lecture of the Chicago Surgical Society was delivered before a joint meeting of the Institute of Medicine of Chicago, Chicago Society of Internal Medicine and the Chicago Society of Medical History and the Chicago surgical, neurologic and pediatric societies, October 3, by Dr. Harvey Cushing, Boston, on "The Cerebellar Astrocytomas."——A joint meeting of the Institute of Medicine of Chicago and the Society of Internal Medicine of Chicago will be addressed, October 27, by Prof. Otfried Foerster, Breslau, Germany, on "Anatomic, Physiologic and Clinical Observations Concerning Chordotomy."——The Chicago Council of Medical Women was addressed, October 3, by Drs. Esther S. Nelson on "Vitamin D," and Mabel M. Matthies, "Vaginal Flagellosis."

INDIANA

Personal.—Dr. Frederick E. Jackson, Indianapolis, was recently elected president of the board of public health, to succeed Dr. Henry S. Leonard. Dr. Herman G. Morgan will continue as secretary of the board of health, and Dr. William A. Doeppers will continue as superintendent of Indianapolis City Hospital.

Society News.—The Indianapolis Medical Society will be addressed, October 21, by Drs. Murray N. Hadley and Lyman R. Pearson on "Cause of Death in Operative Treatment of Gallbladder Disease" and "Cirrhosis of the Liver," respectively. Dr. Edward Starr Judd, Rochester, Minn., will address the October 28 meeting.——The Gibson County Medical Society was addressed, September 8, by Dr. John H. Hare, Evansville, on the feeding of babies.——The Madison County Medical Society was given a banquet at St. John's Hospital, September 9, after which Dr. Edwin N. Kime, Indianapolis, gave an address and conducted a clinic showing the methods of treatment of common skin lesions.

IOWA

Hospital News.—The Iowa State Psychopathic Hospital, Iowa City, announces openings for two resident physicians and two interns each year in psychiatry. These men must have a good general hospital internship to make them eligible as interns or residents of the hospital, and the resident physicians must also have had psychiatric experience. The Iowa Psychopathic Hospital is the clinical basis of the department of psychiatry and is also the psychopathic division of the University Hospital, which, with all its divisions, is the clinical base of the College of Medicine of the University of Iowa.

KANSAS

Society News.—The University of Kansas School of Medicine has announced that the second series in the Porter Lectureship will be given by Dr. Joseph Collins of New York. The subjects are "Medical Progress and the Specialties" (October 13); "Symptoms of Spiritual Starvation" (October 14), and "Success and Satisfaction in the Practice of Medicine" (October 14).

LOUISIANA

Society News.—The Seventh District Medical Society was addressed in Opelousas recently by Dr. Lucien A. LeDoux, New Orleans, on "Some Functional Disturbance of the Ovaries."

Personal.—The board of administrators of Charity Hospital of Louisiana, New Orleans, tendered a reception, October 5, to Dr. Amédée Granger on the occasion of his twenty-fifth anniversary of continuous service as the chief of the department of radiology.

MARYLAND

Sanitation of Soda Fountains. — The Baltimore City Health Department is conducting a campaign to require proprietors of soda fountains to comply with the state law requiring drinking glasses and spoons to be properly cleansed. An act of the legislature of 1912, dealing with common drinking cups, prohibits the consecutive use of cups, glasses, dippers and other drinking vessels in public places without previous cleansing or disinfecting by washing in clean water containing soap or an alkaline detergent, and subsequent rinsing and cleaning in running water or by some other method approved by the state board of health.

Typhoid in Baltimore County.—Health officials attribute the spread of typhoid in Baltimore to infected milk or water in places where patients spent summer vacations. With the definite diagnosis of five suspects by the health officer for Baltimore County, the Woodlawn typhoid outbreak claimed its fortieth case, September 23. There have been eighty-five cases of typhoid in the city since January 1, as compared with fifty-two for the corresponding period of 1921. The Woodlawn outbreak, which was traced to milk delivered by a typhoid carrier, resulted in an order to discontinue the milk supply and the inoculation of all recommended patrons.

MASSACHUSETTS

Reinstatement Refused.—The petition of Dr. Joseph N. Tessier, New Bedford, for reinstatement by the board of registration in medicine was refused, September 11. His registration as a physician in Massachusetts was revoked several years ago.

Fund Selects Site for Rural Health Project.—The Commonwealth Fund has chosen Massachusetts as the second state in which to develop a rural health project under the terms of its new program for cooperation with the state health departments in promoting rural health. The unit for the health service demonstration will be a group of five or six towns with from 15,000 to 25,000 people which voluntarily unite for the purpose. Two such groups will be formed and each will organize a board of health with representatives from the several towns. A field unit will be formed in the state department to promote rural health progress throughout the state and particularly to guide the development of the two centers of intensive work.

Dedication of Sixth Health Unit.—Dedication exercises at the opening of the sixth health unit, established through the George Robert White Fund, were held, September 15, at Boston. Mayor Curley, in accepting the gift on behalf of the city, stated that the whole plan of the health units in Boston was conceived at a meeting held in Boston about fifteen years ago with Drs. Richard C. Cabot, health commissioner, Francis X. Mahoney and Charles F. Wilinsky. The first unit, established in 1915, was so successful that it was the beginning of a series of these units, which are educational institutions functioning for the training of the public in an understanding and practice of health conservation. The dedicatory address was given by Lee K. Frankel, Ph.D., New York, and an address was later made by Dr. Milton J. Rosenau of Harvard University.

MICHIGAN

State Medical Election.—At the recent annual meeting of the Michigan State Medical Society, Dr. Ray C. Stone, Battle Creek, was installed as president; Dr. Carl F. Moll, Flint, was made president-elect; Dr. John R. Rogers, Grand Rapids, treasurer, and Dr. Frederick C. Warnshuis, Grand Rapids, secretary, reelected.

MINNESOTA

Society News.—The eighth annual convention of the Minnesota Congress of Parents and Teachers, to be held, October 28-30, at Minneapolis, will be addressed among others by Dr. Lawrence R. Gowan, Duluth, on "Mental Hygiene." The joint session of the Minnesota State Medical Association, state board of health, division of child hygiene, Northwest Conference of Child Health will be addressed by Dr. William A. O'Brien, Minneapolis, on "New Childhood," and Dr. Morris Fishbein, Chicago, "Foods, Fads and Follies." Presentation of the summer round-up prizes will be made by Dr. Edward A. Meyerding, secretary, state medical society.

Training School for Reserve Officers. — The second annual inactive duty training period for medical reserve officers will be held at Rochester, November 9-23, under the sponsorship of the Mayo Foundation, directed and personally supervised by instructors of the medical board of the U. S. Army detailed for the purpose. The school offers opportunities for officers who have not received summer training to earn 100 hours toward the required number for promotion at the expiration of their respective periods of appointment. The curriculum embraces basic subjects essential to all medical officers and will cover a period of fourteen days of seven hours each. All medical reserve officers are eligible and arrangements have been made to allow visiting officers to attend clinics in the mornings and schools of instruction during the afternoons and evenings. Any physician wishing to join the reserve corps should apply at once for a commission and when commissioned will be qualified to register for the course. Further information may be obtained from Col. Louis B. Wilson, Mayo Foundation, Rochester.

MISSISSIPPI

Personal.—Dr. Sam L. Hutchison, assistant superintendent, Natchez Charity Hospital, Natchez, has resigned to engage in private practice.——Dr. Hernandez Lira, representing the health department of the Mexican government, has recently been making a special study of hookworm disease control in the protection of the preschool child and in maternal hygiene.

MISSOURI

Society News.—The Jackson County Medical Society was addressed, September 23, by Dr. Wilbur A. Baker, Kansas City, on "Gastro-Intestinal and Metabolic Factors in Arthritis"; Dr. Ferdinand C. Helwig conducted a pathologic conference, and Dr. Robert McE. Schauffler, Kansas City, gave an abstract of recent literature on arthritis.——The Jackson County Medical Society was addressed, September 30, by Drs. Wilson A. Myers, Kansas City, on "Spondylolisthesis with Special Reference to the Etiology and Pathology," and Edward P. Heller, Kansas City, "Rôle of Back Injuries in Production of Renal and Perirenal Pathology."——The heart campaign sponsored by the Health Conservation Association of Kansas City was started with the lecture, October 7, by Dr. Leonard G. Rowntree, Rochester, Minn., on "Recent Advances in the Study of Heart Disease."

NEBRASKA

Society News. — Dr. Ephraim Korol, Maywood, Ill., addressed the Omaha-Douglas County Medical Society, September 23, on "Emphysema and Pneumothorax," and Dr. John Jay Keegan, Omaha, "Surgery of the Sympathetic Nervous System," with case reports.——The Ninth Councilor District Medical Society was addressed, September 9, at Grand Island, by Drs. Robert D. Schrock, Omaha, on "Fractures at the Elbow"; Eugene C. Foote, Hastings, "Eye Conditions in India," illustrated; Eli A. Watson, Grand Island, "Surgery of the Upper Abdomen," and Ernest Kelley, Omaha, "The Mechanism of Hysteria."

NEW MEXICO

Personal.—Public health workers from over the state gave a farewell dinner for Dr. George S. Luckett in Santa Fe, August 23. Dr. Luckett recently resigned as state health officer to become professor of hygiene at Leland Stanford

University. He will be succeeded by Dr. Charles W. Gerber, who has been county health officer of Dona Ana County for several years.

NEW YORK

Society News.—The Medical Society of Niagara County was addressed, September 9, by Dr. Claude E. McDermid, Niagara Falls, on "Rôle Played by Spinal Nerves in Functional Disturbances of Digestion."——The Buffalo Academy of Medicine was addressed, October 1, by Dr. Géza de Takáts, Chicago, on "The Causes of Failure in the Treatment of Varicose Veins."

New York City

First Harvey Lecture.—Dr. Robert F. Frank will deliver the first Harvey Society Lecture at the New York Academy of Medicine, October 16, on "The Female Sex Hormone."

Hospital News.—The staff of the Greenpoint Hospital, Brooklyn, with the approval of the commissioner of the department of hospitals, is undertaking an intensive study of diabetes in children. In order to have sufficient cases for study, this condition being relatively uncommon, physicians are requested to direct children suffering from diabetes to this hospital.

Appointments at Columbia University.—The following appointments to the medical faculty of Columbia University have been announced: Crawford F. Failey, Ph.D., and Warren F. Sperry, Ph.D., assistant professors of biologic chemistry; Dr. Rustin McIntosh, to be professor in diseases of children; George W. Bachman, Ph.D., of the School of Tropical Medicine, San Juan, P. R., to be associate professor in parasitology, and Dr. Samuel T. Orton, New York, to be professor in neurology and neuropathology.

Study of Hospital Practice.—The New York Academy of Medicine, in its recent annual report, advocates an intensive study of hospital practice including the qualification of methods of appointing the medical personnel and the methods of recording case history and pathologic observations. Such a course is said to be necessary to guard against unnecessary operations, which are said to be performed in some of the unsupervised hospitals of the metropolitan district. Such a study of hospitals should include public and private hospitals as well as incorporated and unincorporated hospital nursing homes. The officials of the academy predict that, unless some supervision is exercised over some hospital practice, state supervision of all hospitals will follow in the immediate future.

Society News.—Dr. Cyrus C. Sturgis, director, Thomas Henry Simpson Memorial Institute for Medical Research, University of Michigan, Ann Arbor, will deliver the Middleton Goldsmith Lecture for 1930 of the New York Pathological Society, October 18, at the New York Academy of Medicine, on "Recent Development in the Treatment of Pernicious Anemia and a Consideration of the Etiology of the Disease."——The New York Academy of Medicine was addressed, October 3, by Drs. Norman E. Treves and George T. Pack on "The Development of Cancer in Burn Scars."——"Intravenous Urography as a Diagnostic Method" was the subject of Dr. Moses Swick before the Harlem Medical Association, October 3.——The Brooklyn Pediatric Society opened its new season with a meeting, September 24, addressed by Dr. Fred Maurice McPhedran, Philadelphia, on "Child Tuberculosis."

Radium in New York Hospitals.—Radium to the amount of 13.342 grams, worth $1,000,000, is available to the hospitals of New York City, according to a survey of hospital facilities for cancer treatment recently made by the New York Cancer Committee. The survey states, according to *New York Medical Week*, that the present cost of a gram of radium is $70,000. The largest stock of radium in the city is said to be owned by Memorial Hospital, which owns 4 grams and has the use of 4 grams loaned by special trustees. The New York Cancer Institute has the use of 2 grams and Bellevue Hospital has the use of 1, all owned by the department of hospitals. The survey declares that the need for more adequate care for cancer patients still exists, calls for the development of a special cancer hospital, and points out that early diagnosis and treatment either by radiation or by surgery is essential to a successful outcome.

Fraudulent License Returned.—The endorsement to practice medicine and surgery in New York, based on credentials from Wisconsin and given to "Dr. Paola S. Marzio" was recently returned to the state board of medical examiners. Marzio claimed to be a 1928 graduate of the University of Chicago and to have obtained a license to practice medicine in Wisconsin. There is no record at the headquarters of the American Medical Association of a Paola S. Marzio, and, according to information received, there is no record of a Paola S. Marzio ever having been registered in any department of the University of Chicago or of being licensed in Wisconsin. The American Medical Association does have record, however, of a Paul Victor Marzio who claims graduation from both the St. Louis College of Physicians and Surgeons and the Kansas City College of Medicine and Surgery in 1922. Paul Victor Marzio was licensed by the Connecticut Eclectic Medical Examining Board in November of the same year. This license was one of 175 which were revoked, Feb. 1, 1924, following an investigation of the diploma mill and license scandal. On claims being presented that his credentials were fraudulent, the endorsement of Paola S. Marzio was returned.

Campaign Against Venereal Disease.—Officers of the Bellevue-Yorkville Health Demonstration have invited every physician in Manhattan and the Bronx to a series of lectures to be given at the Bellevue-Yorkville Center as follows: October 9, Drs. Shirley W. Wynne, "Public Health Control of Syphilis and Gonorrhea" and Edward L. Keyes, Ithaca, N. Y., "Gonorrhea in the Male, Diagnosis and Treatment"; October 16, Dr. Abernethy B. Cannon, "Diagnosis and Treatment of Syphilis from the Viewpoint of the General Practitioner"; October 23, Dr. Emily D. Barringer, "Gonorrhea in the Female," and October 30, Dr. Isadore Rosen, "Congenital Syphilis, Diagnosis and Treatment." The lectures are a part of the campaign to inform every resident of the health demonstration area of the risk of venereal infection and to get infected individuals under medical care. The campaign is carried on in cooperation with the New York Department of Health, the New York Tuberculosis and Health Association and the American Social Hygiene Association. The public will be reached by pamphlets, posters, exhibits, lectures and motion pictures. Monthly report blanks are to be sent out to physicians and clinics in the district in October, November and December. The information asked is the number of patients under observation or treatment each month.

Program of Third Graduate Fortnight.—The New York Academy of Medicine's third annual graduate fortnight, to be held October 20-31, will feature "Medical and Surgical Aspects of Acute Bacterial Infections." The speakers, among others, October 20 will be Drs. Frank Billings, Chicago, on "Focal Infection as the Cause of General Disease"; Charles F. Martin, Montreal, Canada, "Continued Education of the Practitioner"; October 21, Fenwick Beekman, "Acute Hematogenous Osteomyelitis"; Joseph F. McCarthy, New York, "Acute Infections of the Urogenital Tract"; October 22, John Edmund Mackenty, "Infections Arising from Tonsils and Sinuses"; Isidore Friesner, "Infections of the Middle Ear (Acute Systemic Infections from the Ear)"; Henry Sage Dunning, "Acute Infections of the Face and Oral Cavity"; October 23, Frederic W. Bancroft, "Operative Risks from Infection"; Eugene H. Pool, "Appendicitis"; Walton Martin, "Bacteriemia"; October 24, William L. Keller, Washington, D. C., "Complications Incident to Delayed Diagnosis in Suppuration of the Lung and Pleura"; Allen O. Whipple, "Acute Infections of the Gallbladder and Biliary Tract"; October 27, George W. Kosmak, "Introductory Remarks on the General Subject of Puerperal Mortality and Its Reduction"; John Whitridge Williams, Baltimore, "Clinical and Pathologic Notes on Puerperal Infection"; John Osborn Polak, Brooklyn, "Puerperal Infections and Their Present Therapy"; October 28, Franz d'Herelle, New Haven Conn. "Bacteriophage as a Treatment in Acute Medical and Surgical Infections"; Frank L. Meleney, "Infections of the Skin and Subcutaneous Tissue-Including Infections of the Fingers and Hand"; Rufus I. Cole, "Acute Pulmonary Infections"; October 29, William H. Park, "Serum Therapy"; October 30, Ernest E. Irons, Chicago, "Facts and Fancies Concerning Vaccines and Non-Specific Therapy"; Homer Smith, "Rheumatic Fever"; October 31, Emanuel Libman, "Acute and Subacute Bacterial Endocarditis," and William W. Herrick, "Meningococcus Infections, Including Meningitis." Dr. Hans Zinsser, Boston, will deliver the Carpenter Lecture, October 29, on "Immunity—General and Local."

NORTH DAKOTA

Society News.—The Cass County staff of district physicians, members of the county board of health and the county public health nurses, held a conference, September 6, as guests of Dr. Albert M. Limburg, county superintendent of health. Addresses were made, among others, by Drs. John B. James, Page, on "Cooperation in Community Interests"; Harry J. Gowenlock, Gardner, "The Public Health Nurse," and Edward H. Richter, Hunter, "The Dental Care of School Children." John C. Pollock, Cass County state's attorney, spoke on "Promotion of Health—Legal Aspects."

OHIO

Milk Examined for B. Abortus.—The health commissioner of Clinton County and the city of Wilmington is making a drive for the elimination and prevention of undulant fever. Several cases have been found. Advertisements are run in the press stating that "any person in Clinton County, Ohio, who retails raw milk from cows that have not been tested for contagious abortion will be prosecuted."

Health Commissioners Have a New Duty.—Under the 1929 Ohio general election law, which became effective, Jan. 1, 1930, the health commissioner of a registration city is required to make monthly reports to his board of elections of the names and residence addresses of all persons, over 21 years of age, who have died within the city during the month, for elimination by the board from the registration list. The provision of law follows:

> *Sec. 4785-46. Notices of deaths and convictions.* The chief health officer of each registration city shall file with the board, at least once each month, the names and residence addresses of all persons, over twenty-one years of age, who have died within such city during the month, and the board shall cause all such names as appear upon the registration lists to be removed therefrom. . . .

The secretary of state, as head of the state's election machinery, has prepared a legal form for submitting these reports, known as "Form No. 248; Prescribed by the Secretary of State." It may be obtained by health commissioners on request to their boards of elections.

PENNSYLVANIA

Philadelphia

Society News.—The Philadelphia County Medical Society was addressed, September 24, by the retired president, Dr. John A. McGlinn, on "Responsibility of Organized Medicine to Combat the Evils That Threaten Scientific Medicine." The scientific program of the society, October 8, consisted of a symposium on blood diseases.——The new college building of the Woman's Medical College of Pennsylvania was formally opened, September 24; among others, Dr. Donald Guthrie, Sayre, delivered an address on "The Modern Medical Graduate —Ambassador of Health."

Institute for Mental Hygiene.—The Pennsylvania Hospital has announced the opening of its new Institute for Mental Hygiene and requests cooperation in finding a new type of medical patient and in finding a fair rate of charge for patients of moderate means. The clinic is planned for patients who will meet the physician more than half way in recognizing that they need help for fatigue cases, fears, maladjustments, and difficulties with getting on with other people or at their work. Mental factors as well as physical will be sought out and treated. Classes in occupational and physical therapy, music and recreation can be used by outpatients or by the patients of any member of the county medical society who wishes to make arrangements for them with the occupational or physical director. Children will be received in the outpatient department and in the Franklin School for problem children. The institute is not licensed and cannot receive any committed patients. It will be greatly interested in toxic mental disturbances and in problems concerning general convalescence. An experiment in medical economics is planned.

RHODE ISLAND

Society News.—The Providence Medical Association was addressed, June 2, by Drs. Frank W. Dimmitt, Jr., on "Some Recent Advances in Otolaryngology," and James L. Gamble, Brookline, Mass., "Pathogenesis of Acidosis and Alkalosis."

SOUTH CAROLINA

Society News.—The annual meeting of the Seventh District Medical Association, September 11, at Kingstree, was addressed, among others, by Drs. Hal M. Davison, Atlanta, Ga., on "Neurosis in Internal Medicine"; Lester A. Wilson, Charleston, "Antepartum Hemorrhage"; Edwin P. Alyea, Durham, N. C., "Invention and Application of Uroselectan," and Charles J. Lemmon, Sumter, "Reconstructed Fractures of the Forearm."——The Greenville County Medical Society was addressed, August 4, by Drs. Charles P. Corn, Greenville, who talked on "Modern Conception of Dermatology and Syphilology."——The Spartanburg County Medical Society was addressed, August 25, by Dr. Edgar A. Hines, Jr., Seneca, on sprue, with report of a case; Dr. Sam H. Ross, Jr., Blaney, reported a case of gangrene of the colon and terminal ileum caused by an unknown bacillus very similar to the dysentery bacillus.——Dr. Harold L. Amoss, Durham, N. C., addressed the Columbia Medical Society, September 8, on "Unusual Complications of Brucella Infection," and Dr. Foster M. Routh, "Common Sense in Allergy."

VIRGINIA

Society News.—The Clinch Valley Medical Society, at its annual fall meeting, September 20, at Norton, was addressed by Drs. Manfred Call, Richmond, on medicine; Harry H. Ware, Jr., obstetrics; St. George T. Grinnan, diseases of children; Charles R. Robins, surgery; Ennion G. Williams, state health commissioner, health problems, and James Allison Hodges, clinical education.

WASHINGTON

Society News.—The tenth annual convention of the Public Health League of Washington at Mount Baker Lodge, September 2, was addressed by Dr. Horace J. Whitacre, Tacoma, on "Economics in the League," in which he brought up the problems which confront the medical profession and the legislative measures pertaining to health that are anticipated to be introduced at the coming legislative session.——The economic and specialty section of the King County Medical Society was addressed, September 29, by Drs. Ivan M. Woolley, Portland, Ore., on "Use of Lipiodol in X-Ray Diagnosis of the Accessory Sinuses," and Harold E. Nichols, Seattle, "X-Ray Diagnosis of Bone Tumors."

WEST VIRGINIA

Society News.—Dr. Frank C. Hammond, Philadelphia, delivered an address on "Genital Bleeding" at the Davis Memorial Hospital, Elkins, September 9.——The Harrison County Medical Society was addressed at Clarksburg, September 4, by Dr. Chester R. Ogden on "European Clinics."

WISCONSIN

Personal.—Dr. Lenwood M. Keene, former physician on the Lac du Flambeau Indian reservation, has been transferred to the Pawnee, Oklahoma, reservation.——Dr. Francis B. McMahon, Milwaukee, won the president's cup at the annual golf tournament, September 13, held during the session of the State Medical Society of Wisconsin.

University News.—Drs. Herman C. Schumm, Jr., and Walter P. Blount, Milwaukee, have been appointed to the orthopedic surgery staff of Marquette University School of Medicine. Dr. Schumm will be associate clinical professor and director of orthopedic surgery at the Milwaukee County Hospital and the Milwaukee Children's Hospital. Dr. Blount will be clinical instructor in orthopedic surgery at the medical school.

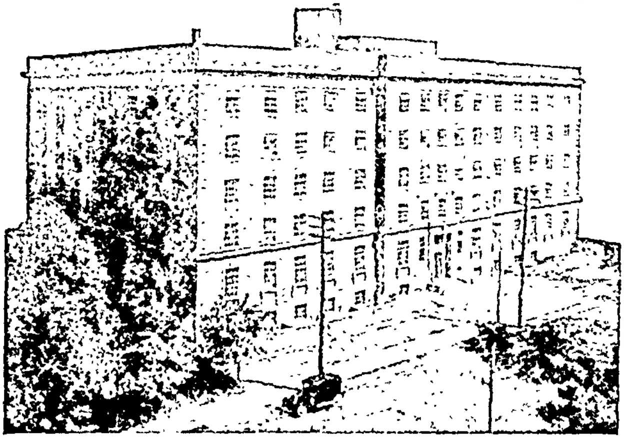
CANADA

Society News.—The seventh annual convention of the Ontario Hospital Association was addressed at Toronto, October 1-3, among others, by Drs. Clarence B. Farrar, Toronto, and Bernard T. McGhie, Orillia, on "Relation of the Mental to the General Hospital; Walter F. Langrill, Hamilton, and Ward A. W. Woolner, Ayr, hospital medical organization, and William J. Dobbie, Weston, "The Financial Responsibility for Schools for Nurses."

Tuberculosis Scholarship Tour.—Fifty-four physicians made up the British scholarship tour of the British tuberculosis sanatoriums of the Dominion and the United States in connection with the recent meeting of the British Medical Association at Winnipeg. The party was headed by Dr. Ernest Ward of Devonshire, the honorary secretary of the Joint Tuberculosis Council of Britain which organization coordinates all the tuberculosis work in England, and included, among others, Drs. John Rennie, medical officer of health of Sheffield; G. B. Price, tuberculosis specialist of the British Ministry of Health; D. A. Powell, president of the Welsh Medical Association, tuberculosis officers, consulting physicians and bacteriologists, each of whom was assigned a special branch of the subject for study to be written up on his return to England.

Opening of the Banting Institute.—Ceremonies in connection with the opening of the new $800,000 Banting Institute of the University of Toronto were held, September 16, with Lord Moynihan, president of the Royal College of Surgeons of England, presiding. The cost of the building was contributed by the provincial government, the university and the Banting Research Foundation, which raised funds by popular subscription. It is estimated that when fully equipped the institute will cost over $1,000,000. The building replaces the old pathologic building of the university and will combine its activities with the general hospital. It commemorates not alone the growth of medical science and the advancement of the

Toronto University but also the name of the Toronto graduate responsible for the discovery of insulin, Dr. Frederick Grant Banting. A tunnel under the roadway at College Street connects the hospital and the institute. The sub-basement of the institute contains necropsy and pathologic museum rooms; the first floor is devoted to laboratories in surgical and neurologic pathology and bacteriology, and has a theater seating 250 and a pathologic library. The third floor is for classes. The architectual beauty is best noted in the large library on the third floor with its gray stucco ceiling and parquet floor. Over the fireplace in this room is a portrait of Lord Lister presented to the institute by Dr. Edmund St. George Baldwin and the late Dr. F. LeM. Grasett who, years ago, was associated with the discoverer of antiseptic surgery at the Glasgow Royal Infirmary. Dr. Banting occupies the top and fifth floors of the building, together with seventeen physicians and scientists who collaborate in research. The department has for the first time full-time professors. Other floors contain laboratories for research and pathologic study, and the roof is occupied by pens for experimental animals. The provincial government has a pathologic laboratory in the building where its own staff will analyze specimens pertaining to the public health of the province. Coincident with the opening of the Banting Institute, a rearrangement of the various departments will be effected. The Institute of Radiotherapy will be enlarged at an investment of nearly $150,000, for the study of the effect of radium, roentgen rays and allied agents. An emanation plant will be incorporated for which work 500 mg. of radium has been set aside, and emanations will be made available for distribution to any reasonable distance. The essential purpose of the institute is to aid research and to enable students to experiment and evolve theories of their own. At the opening ceremonies, the degree of doctor of laws was conferred on Lord Moynihan; Mr. C. S. Blackwell, chairman, board of trustees, Toronto General Hospital, and Dr. Thomas S. Cullen of Johns Hopkins University School of Medicine, and the degree of doctor of science on Dr. Davidson D. Black of the University of Peiping on account of his anthropologic finds in Tibet, and Ambrose T. Shanton of the English government service.



The Banting Institute.

GENERAL

Society News. — Dr. Alexander B. Moore, Washington, D. C., was installed as president of the American Roentgen Ray Society at its annual meeting, September 25; Dr. Leopold Jaches, New York, was made president-elect and Dr. John T. Murphy, Toledo, Ohio, secretary, reelected. The next annual meeting of the society will be held at Atlantic City in September.

Report of United Fruit Company. — During 1929 the United Fruit Company provided medical treatment for 68,965 employees and 102,256 nonemployees. It maintains hospitals and dispensaries at Port Limon, Costa Rica; Almirante, Panama; Quirigua, Guatemala; Tela, Honduras; Puerto Castilla, Honduras; Preston and Banes, Cuba; Puerto Armuelles, Panama; Santa Marta, Sevilla and Aracataca, Colombia, and dispensing service in the ports of New York, Boston and New Orleans. Malaria is of the greatest economic importance in the tropics because of its prevalence, chronicity and debilitating effects on the population. Since 1926, when an intensive campaign for malaria control was inaugurated, the greatest improvement has been noted in children. The report covers sanitation in the tropics, steamship sanitation and the work done at the snake farm at Lancetilla, Tela, Honduras, by the Museum of Comparative Zoology, Harvard University, the United Fruit Company and the Mulford Biological Laboratories. Snakes are collected and antivenin produced under the direction of the Antivenin Institute of America. In a population of 150,000 people in the West Indies and Central America, the annual rate of snake bites was 23 and the mortality 1.06 per hundred thousand. Among the diseases treated by the medical department of the company were 7 cases of leprosy; 106 cases of typhoid with 18 deaths; 325 cases of amebic dysentery with 6 deaths, and 566 cases of hookworm disease with no deaths.

Bequests and Donations.—The following bequests and donations have recently been announced:

Hospital and House of Rest for Consumptives at Sprain Ridge, Yonkers, N. Y., $12,464 by the will of the late William H. Erskine.

United Israel-Zion Hospital, Brooklyn, $10,000; Beth Israel and Mount Sinai hospitals, $7,500 each, and Jewish Maternity Hospital, New York, $2,500, by the will of the late Morris Meiselman.

Mansfield General Hospital, Mansfield, Ohio, $5,000, from Edward W. Loughridge in memory of his parents.

The Roosevelt Hospital, $1,000,000; Manhattan Eye, Ear and Throat Hospital, New York, $100,000; and St. John's Riverside Hospital, Yonkers, N. Y., $50,000, through the will of Lloyd W. Seaman.

St. Vincent's Hospital, New York, $22,500, by the will of Mrs. Alice Harrington Santher.

The Elyria Memorial Hospital, Elyria, Ohio, $45,000, through the will of Mrs. Carrie A. L. Patch. The hospital is to receive the income from the trust fund, and it will be used for the Gates Hospital for Crippled Children.

Presbyterian and Pennsylvania hospitals, Philadelphia, will each receive one third of an estate of $200,000, through the will of William Snodgrass.

The Methodist Episcopal Hospital, Brooklyn, $10,000, from the estate of Simon J. Harding.

The Foote Hospital, Jackson, Mich., a second gift of $50,000 by Capt. William Sparks.

Hospital of the University of Pennsylvania and Pennsylvania Hospital, Philadelphia, each $150,000 by the will of the late Mrs. Elizabeth B. Ketterlinus. The bequest to the University Hospital is to be held in trust and the proceeds devoted to the John G. Clarke fund for the benefit of Ward K. The legacy to the Pennsylvania Hospital is also left in trust.

FOREIGN

University News.—At the Encaenia, held June 25, at the University of Oxford, the honorary degree of D.Sc. was conferred on Sir Arthur Keith, conservator of the Museum of the Royal College of Surgeons of England.

Personal. — Dr. Sigmund Freud, Vienna, was recently awarded the Goethe prize by the German city of Frankfurt, in recognition of researches in psychoanalysis. It is said that Goethe's essay on Nature awakened Freud's desire to be a physician.——Dr. Karl Sudhoff, formerly professor of history at Leipzig, has been elected a foreign member of the Hungarian Academy of Sciences at Budapest.——The William Mackenzie medal for "original contributions to ophthalmology of outstanding merit" has been awarded to Prof. J. van der Hoeve, Leyden, Holland. He delivered an address at the Glasgow Eye Infirmary, October 3, on "Ophthalmology in Its Relation to the Other Branches of Medical Science."

Government Services

Army Personals

Major Daniel J. Hayes, Letterman General Hospital, Presidio of San Francisco, Calif., for the convenience of the government, proceeded to his home about September 30 to await retirement; Major Martillus L. Todd, on the expiration of his present leave of absence, for the convenience of the government will proceed to his home and await retirement; Lieut. Col. Mathew A. Reasoner will report to Medical Field Service School, Carlisle Barracks, for the purpose of pursuing advanced course of instruction, on completion of which he will proceed to St. Louis and assume command of the St. Louis medical depot; Major William J. Burdell, having been found by an army retiring board incapacitated for active service on account of disability incident thereto, and such finding having been approved by the President, the retirement of Major Burdell from active service on September 30 is announced; Lieut. Col. Daniel P. Card, assigned to duty at Letterman General Hospital, San Francisco; Capt. John H. Dawson, assigned to duty at Fort Sill, Oklahoma; Capt. Horace J. Caterer, Fitzsimons General Hospital, Denver, for the convenience of the government, proceeded to his home about September 30 to await retirement.

Foreign Letters

LONDON

(From Our Regular Correspondent)

Sept. 20, 1930.

The Improvement of the Race

In an address before the ninth annual meeting of the International Federation of Eugenic organizations, Sir Arthur Keith considered the effect of modern civilization on man. Was the generation growing up as fit in body and mind as the one it would replace? Was there evidence of deterioration? If civilization was tending to exchange ability for mediocrity, measures would have to be discovered to alter this. He hoped that the forces which had raised man to his present status would raise him still higher. He approached eugenics with the eye of the prehistorian. There were only two chapters in man's evolutionary history. The first began with emergence from the Pithecanthropoid stage and ended with the full-blown types of humanity such as were found in Europe and South Africa toward the end of the last ice age. In that phase, progress was effected amid natural surroundings. Then, 10,000 years ago, man's evolution proceeded under new conditions—those seen in cities, conditions which were no longer made by nature but by man. In the first or natural stage the production of the race was everything; in the second the production of the race was sacrificed to the accumulation of wealth. In both phases humanity walked toward its fate with eyes closed. If eugenists had their way a new phase—a conscious phase—of evolution would be initiated. If it was found that the way man lived was leading to mental and physical bankruptcy, people could no longer afford to be mere pawns on the chessboard of evolution: they must take a hand at the game. The chief difficulty before eugenists was human nature, which was dominated not by reason but by passion, feeling, emotion, prejudice and instinct. Eugenic reform depended on the extent to which human nature could be rationalized. There were signs that the times were favorable. The public of all countries was more willing to listen to eugenic proposals than at any previous period. The highest dignitaries of the church were now seeking to open a way for the eugenist. They had removed the tabu that surrounded the processes of reproduction. At the meeting they were fortunate in having to welcome Major Leonard Darwin, the Nestor of English eugenics. Seventy years had gone since his father published "The Origin of Species.". That book had moved the world toward eugenic reform more than any other.

Mr. C. J. Bond, a surgeon, gave some facts pointing to deterioration of the population. The examination of 2½ million men of military age in 1918 showed that only one third were perfectly healthy and fit. The loss from sickness among insured persons in England and Wales in 1928 amounted to 26½ million weeks. (It should be remembered that a certain amount of this is due to malingering and lax certification.) The first step should be a fuller ascertainment of the real position, a national stock taking of mental and bodily qualities in different social groups. The next step was to cease breeding from inferior stocks and to promote larger families in the superior. Sterilization duly safeguarded, in combination with segregation, must be the method to prevent procreation of the defective, irresponsible and antisocial, who largely composed the subnormal lowest social group.

Leonard Portal Mark: The Physician Who Described Acromegaly in Himself

The death at the age of 75 years of Dr. Leonard Portal Mark removes an heroic figure, who, stricken with acromegaly, bore his sufferings not only with fortitude but with equanimity and turned them to account for the benefit of medical science. Born at Marseilles in 1855, the son of the British consul there, he was educated in France and entered St. Bartholomew's Hospital, London, from which he qualified in 1879. He settled in London as a general practitioner and, possessing artistic talent, also undertook the work of pathologic artist at his hospital. Although he was skilled in the detection of disease in others, the onset of acromegaly was so insidious that he did not recognize it in himself for thirteen years. In his autobiography he wrote: "I suddenly became aware that I was the subject of a peculiar and rare disease. Great was my surprise when I learnt shortly afterward that the fact was well known to my medical friends, who had watched its steady development for fifteen years or more. Each day when I looked into the glass to brush my hair, there was a typical acromegalic literally staring me in the face. Yet I never recognized the fact." The disease ran its usual course with severe headache, but Dr. Mark never repined in the least and turned his misfortune to account for the benefit of medical science. Other physicians before him have described their own maladies. The most illustrious is Sydenham, "the English Hippocrates," who used his own experience as a basis for his classic description of gout; but no such minute account as was given by Mark of his own case has ever been published by a physician. Moreover, it would be impossible to surpass the philosophical detachment with which he viewed his malady; he described it exactly as if it had been an interesting case in another person. He carefully recorded his symptoms and had photographs taken from time to time and finally left directions that his skull and brain should be examined by a competent pathologist. As long as was possible he did his daily work without any repining. His first book, "Acromegaly: A Personal Experience," appeared in 1912 and fifteen years later a supplement entitled "The Apologia of an Acromegalic." He recorded the changes that took place in his eyes, his skull and his brain and obtained written opinions from eminent authorities on various points in his case. He minutely recorded his subjective symptoms—the headache, lethargy, tinnitus and feelings of depression. It is noteworthy that the disease did not seem to have in the least shortened his life. In a tribute in the *British Medical Journal* Dr. F. R. B. Atkinson writes: "Always interested in his malady, he was ever ready to hear anything concerning it found in the literature. Ever suffering great discomfort during the fifty years of his illness, often in extreme pain, he never gave in. The last time I saw him he was deaf, nearly blind, could hardly walk and was suffering from various complications connected with his disease. His last words uttered to me not long since were 'I have much to be thankful for.' The medical profession is honored by such a one."

Arsenic in "Cough Drops"

A curious outbreak of arsenical poisoning has been reported from Stoke-on-Trent. A physician reported to the health officer that twelve children had been taken ill after eating certain sweets ("cough drops"), which had all been purchased in one shop. The symptoms were the same in all the cases—gastric irritation followed by vomiting, which in the mildest cases lasted six or seven hours. Analysis of the sweets revealed large quantities of arsenic. Then a similar outbreak due to the same kind of sweets occurred in another district. The premises of the manufacturer were visited by the health authorities. The ingredients of the sweets were found to be white sugar, brown sugar, dextrose and flavoring of camphorated tincture of opium and peppermint and other volatile oils. But it was also found that a dusting powder had been used, which proved to be pure arsenic trioxide. In several analyses of the sweets the quantities of arsenic varied from 77 to 150 grains of arsenic to the pound, and some of the sweets contained as much as two-thirds grain in each one. The large quantities of arsenic used as dusting powder in the manufacture had permeated almost all the ingredients of the works and arsenic was found in considerable quantities in treacle and other substances. The source of the dusting powder seems to have been a box of arsenic trioxide left by a previous tenant who made enamel letters for shop windows. How it came to be used as a dusting powder is not explained. It is fortunate that in spite of the heavy contamination with arsenic there were no deaths. The manufacturer and his son suffered from arsenical irritation of the skin as well as from pains and diarrhea due to eating food with hands contaminated in the making of the sweets.

Birth Rate Lowest on Record

The registrar-general's medical tables for 1929 have just been issued. The birth rate was 16.3 per thousand living at all ages, once again the lowest recorded since the establishment of civil registration in this country, the lowest previous rates being 16.6 for 1927 and 16.7 for 1928. The death rate was 13.4 against 11.7 in the previous year; it is the highest since 1919, which had a figure of 14 but, because of the war, was based on the deaths of civilians alone. The increase in the death rate was due almost entirely to the high mortality from respiratory and circulatory diseases and the influenza epidemic during the abnormally severe weather of February and March. The deaths of infants under 1 year were 74 per thousand live births, or 9 above those of 1928. Here again the excess was due to the high mortality of the March quarter. Excepting the pandemic of 1918-1919, the epidemic of influenza was the most severe in this country since the disease reappeared in 1890-1891, the mortality being 734 per million living, against 196 in 1928. Deaths from accidents due to mechanical vehicles on the roads increased from 4,492 in 1927 to 5,251 in 1928 and 5,799 in 1929.

Another Martyr to the X-Rays

The roll of martyrs to the ignorance of the need of protection against the x-rays in the earlier period of their use unfortunately is not completed. Mr. E. H. Harnack, who is now 65 years of age, was one of the pioneers of the use of the x-rays. He is in the London Hospital awaiting the removal of the remaining portion of his right hand. For more than twenty-five years he has served the hospital, first as a photographer and then as radiographer in the earlier experimental work with the x-rays, in association with Dr. Sequeira, the former dermatologist to the hospital. As a result, he contracted roentgen cancer. Already he has lost the whole of his left hand and the fingers of the right. Some time ago the right thumb became affected and it is now necessary to amputate at the wrist. He has undergone some dozen operations on his right hand. When he became incapacitated for further work the governors of the hospital granted him a pension and he also received one from the Carnegie trustees. From the new x-ray plant of the hospital no one has ever suffered. Twelve of the pioneers in the use of x-rays in this country have died from malignant disease following burns due to their occupation and few have escaped without amputations.

Professor Bequeathes His Body to Hospital

Prof. H. H. Turner, the eminent astronomer, Savilian professor of astronomy at Oxford, who died recently at Stockholm, requested that his body should be used for scientific purposes and left it to the Stockholm Hospital. He also desired that no ceremony, civil or religious, should be used in connection with his burial. Swedish law, however, directs that a ceremony of some kind must follow death. Therefore the hospital could not accept the bequest. Stockholm communicated with the London Hospital, which agreed to accept the professor's body for scientific use. Enclosed in a leaden coffin, it has arrived at the hospital.

PARIS

(*From Our Regular Correspondent*)

Sept. 17, 1930.

The Evolution of Spirochetes

Before the Société de biologie, Levaditi and Li Yuang Po recently presented a communication on the evolutional cycle of *Spirochaeta pallida, Spirochaeta pertenuis* and *Spirochaeta cuniculi.* These spirochetes have a cycle in which one of the phases is represented by parasites arranged in more or less compact chains and circular masses. This stage precedes that of the transformation into nearly ultramicroscopic granules. Various phases of this evolutional cycle may be found in the lesions of the skin and the mucosa, and in the brain of patients with dementia paralytica. Such brains, stained by the Dieterle method (silver impregnation), show in places spirochetes in the evolutional stage, in chains and compact masses, and also the process of transformation into ultramicroscopic granules.

The Bandage Sign

P. Emile Weil has brought up again a study of the *signe du lacet,* or the bandage sign, which consists in the appearance, in certain subjects, of fine petechiae when a moderately tight bandage is applied to the arm, near the elbow, for a period of six minutes. This sign, previously described by Weil and Chalier, and by Frugeni in severe purpura, is observed in hemogenia, in hemophilia-hemogenia and in the hemorrhagic states occurring in liver patients. In a communication to the Société des médecins des hôpitaux de Paris, Weil states that the sign occurs in primary splenomegalia in liver patients, plethoric subjects, persons who are carriers of congenital angiomas, and sometimes also in persons with varicose veins. The author points out that the sign enables one to detect the fragility of the capillaries, and that it throws light on the functional condition of the liver and the spleen, the organs that are in chief control of the tonus, and the formation of the microscopic vascular system.

Lack of Magnesium in the Human Organism

As a result of publications of Professor Delbet and of his widespread propaganda in support of the idea that cancer is due to an insufficiency of magnesia in the body fluids, the magnesia treatment is becoming exceedingly popular, and many persons today are forcing themselves to swallow every morning a lozenge composed of magnesium chloride and magnesium bromide, by way of precaution. The treatment seems to agree with some; they get rid of constipation and find themselves in possession of increased physical and nervous vigor. Delbet has endeavored to discover why civilized peoples today are not so abundantly supplied with magnesium by their food as they formerly were. The alimentary contributions to the magnesium supply of the organism are made chiefly through the salt, the bread and the vegetables. The gray salt of olden times, now abandoned because it is too hygroscopic, contained 1.7 per cent of magnesium chloride and magnesium sulphate, whereas white salt contains only 0.4 per cent of those substances. White flour contains 0.011 per cent of magnesium, whereas the feed reserved for cattle contains from 0.07 to 0.116 per cent. Other animals are thus better off, in this respect, than man. Then, too, the magnesium content of plants varies, depending on the quality of the soil in which they are raised, between 1.32 Gm. and 13.58 Gm. (potatoes). Furthermore, while fertilizers are frequently employed to restore the phosphorus, the calcium and the potassium to the soil deprived of these substances, this is seldom if ever done for magnesium. Here is an oversight that the author wishes to see adjusted, especially in the regions in which cancer abounds. Mr. Lapicque, professor of physiology at the Sorbonne, is not yet fully convinced of the rôle that Delbet ascribes to the lack of magnesium in the production of cancer. But, while he is waiting for this to be proved by the pathologists, he admits that the present diet of civilized man tends to diminish the magnesium intake. It would be easy, he says, to improve the fertilizers by employing magnesium-containing lime substances. By each harvest of beets (*betteraves*), for example, the soil is deprived of 80 Kg. of magnesium per hectare (about 70 pounds per acre). It is difficult today to induce the general public to renounce the use of fine white flour, which has a low mineral content. As a remedy, Lapique recommends the American practice of dredging certain foods with bran and of eating bran muffins for breakfast.

The Birth Rate of Europeans in French Colonies

In the *Presse médicale,* Dr. Legendre, who has spent many years in the colonies, calls attention to the differences that exist in the number of children to a family, in those regions. The number is high in Indo-China, smaller in western Africa, and greatly reduced in Equatorial Africa. Legendre endeavors to ascertain the causes, which, though complex, may be traced to one fundamental cause. The fecundity is in direct proportion to the material comforts enjoyed by the European colonists rather than to the salubrity of the climate. In Indo-China, in a European population of 9,903, of whom 3,445 are adult men and 2,593 are adult women, there are 148 children to each 100 women. In western Africa, where the number of women is diminished, because the home comforts are fewer, since there are fewer large European towns and more isolated stations, in a population of 15,399, or much greater than that of Indo-China, one finds 9,673 men, 3,517 women and 2,209 children, or 34 women to 100 men, and about 62 children to each 100 women; thus, as in Indo-China, about two children per family. In Equatorial Africa, which is just as salubrious as the colonies mentioned, there are only 2,502 Europeans, or 2,010 men, 389 women and 103 children, which is 19 women to 100 men, and 26 children to 100 women, or not much more than one child to a family. Legendre expresses surprise at this restricted birth rate. It is not due to a lack of opportunities for medical care, for there are, in all these centers, well organized maternity hospitals, competent physicians and capable midwives. He finds only one explanation—namely, in the colonies of Africa, there were, in the beginning of the colonizing period, when the life led was primitive, only men to be found. Many civil and military posts were given only to unmarried men—especially the dangerous posts, for the reason that the government, in case of the death of the civil or military officer, preferred not to pay a pension to a widow and children. But that early stage of civilization has passed. Married men are now admitted to all posts; but many prefer to leave their wives and their children in France, in order that the latter may secure a more thorough education in the *lycées,* and also to avoid changing their domicile so frequently as the colonial administration demands of its officials. Furthermore, the dwellings of the officials are, as a rule, better adapted for a single man than for a family. If larger and better dwellings are erected, Mr. Legendre states, more women will come to the colonies and there will be more children.

Camps for Children

The Association de campements de vacances pour les enfants, which was founded in France, a few years ago, is performing an excellent service. Last year it provided sojourns in fresh-air camps for 4,000 children whose parents did not have the means to give them such outings and who otherwise would have had to remain, during that time, in the less healthful atmosphere of the cities. It has recently been decided to locate some of these camps at mountain health resorts, where the children may have the benefit of the pure air and the wholesome surroundings. Dr. Meillon has established one such camp at Cauterets; Dr. Molinéry another one at Luchon, and the resort of St. Honoré-les-Bains has just created one at the suggestion of Dr. Du Pasquier. The first two are installed in tents, out in the fields; the last mentioned is quartered in a large building ordinarily left vacant during the summer vacation. The children are accompanied by leaders who conduct for their benefit daily hikes through the surrounding country, and who take them also, every morning, to the bath establishment for their daily treatment. It appears as if these camps for children would become general at the various health resorts in France.

Retirement of Prof. H. Hartmann

Professor Hartmann, having reached the age limit, is resigning his professorial chair of clinical surgery at the Faculté de médecine de Paris, and also his service in the Hôpital de l'Hôtel-Dieu, where Professor Cunéo has succeeded him.

Palmar Mycotic Keratosis

Dr. Olympio da Fonseca, Jr., recently delivered a lecture at the Academia Nacional de Medicina on palmar mycotic keratosis, on which subject he has made extensive studies in collaboration with Dr. A. Ferreira da Rosa. The speaker said that the disease was observed first in Brazil in 1891 by Dr. Alexandre Cerqueira, a professor at the Faculty of Medicine of Bahia. Aldo Castellani, after interesting studies on the subject, which he began at Ceylon in 1905, succeeded in isolating the etiologic agent, which is a type of imperfect fungus of the genus *Cladosporium.* The disease begins as many small dots, either isolated or in small groups, in one or both hands, or sometimes in other parts of the body. The small dots increase in number and in size after several months of evolution, and when the lesion has completely developed they become confluent, forming one lesion in the form of patches of an irregular contour. As a rule these patches extend several centimeters and have slightly elevated borders. The surface of the patches vary from light brown to an almost black coloration, which may be either uniform in the entire lesion or show some spots of more or less intense hue. The surface of the dermatic lesion is smooth and it has an almost imperceptible desquamation. Mycotic keratosis is not associated with pruritus, inflammatory phenomena or erythema. When erythema is observed as a complication, it should be considered as caused by some other influence. The symptoms of the disease are uniform. As a rule, if treatment is discontinued as soon as an apparent cure is obtained, the disease reappears. At examination the fungi appear under the form of septated or ramified mycelian filaments, either curvilinear or rectilinear. The mycelian filaments present a hyaline or slightly chestnut color and they are either isolated or reunited in faggots. In the scales, isolated and short elements, either unicellular or pluricellular which correspond to real thallospores, are found.

Apophyseal Incomplete Fractures

Dr. A. Amorin read a paper before the Sociedad de Medicina y Cirugia on the frequency of isolated apophyseal incomplete fractures. The speaker stated that fractures of the larger and of the smaller tubercles of the humerus, of the epitrochlea, of the epicondyle and of the styloid process of the ulna are frequent though they have been considered rare. The speaker reported two cases of fractures of the larger tubercle of the humerus, four of the apophysis of the distal end of the humerus and some other fractures of the styloid process of the ulna. These fractures were observed without association with any trauma of the respective joints. The speaker stated that these fractures are considered as being rare not because they are so but because they are often overlooked or are considered as simple dislocations or sprains. Incomplete or apophyseal fractures frequently are erroneously diagnosed as traumatic arthritis. Though the last mentioned condition may be present in rare instances, as a rule the fracture is the factor which determined painful manifestations, hydrarthrosis and local irritation of the synovial membrane, caused by the presence of a lost fragment which acts as an intra-articular loose body. The author emphasized the necessity of roentgen examination in every case of articular trauma, the more frequent use of which should indicate the real cause of pseudo-arthritis. The speaker gave a brief review of some cases and detailed the harmful sequels that may follow a mistaken diagnosis.

Epinephrine in Urethral Applications

Dr. E. Lins read a paper before the Sociedade de Medicina e Cirugia on the good results obtained by the use of epinephrine hydrochloride for urethral application to overcome the difficulties offered to the passage of sounds for catheterization in cases of acute retention of urine caused by urethral stenosis. As these conditions are caused in part by the edema present and in part by spasm, the application of a 1:1,000 solution of epinephrine to the urethra is useful. In several cases Dr. Lins obtained good results by means of the application of epinephrine to facilitate the passage of a filiform catheter, thus permitting the use of some other therapeutic administrations.

The Medical Congress

The third annual scientific meeting of the Medical Association of South Africa was held at Durban this year at the end of July. This year's session was held under the new rules, which were on trial, and the results of the experiment are interesting. It has always been felt that sectional meetings, especially in a country like South Africa where specialization is still in its infancy, precluded many from taking full advantage of the congress. What was wanted was some arrangement whereby men interested in various specialties could join together to discuss subjects of common interest. This arrangement has been found in the "plenary meetings," at which all sections were represented and for which subjects of common interest were chosen. Unfortunately the choice of the selection committee was not always good, and the first plenary meeting was occupied largely with the discussion of a matter of political rather than professional interest.

MEDICAL EDUCATION OF THE BANTU NATIVE

This was the education of the native to help in the medical services of the native territories. The medical service in these districts beyond the Kei, which are populated almost entirely by natives and where the small white settler communities hardly hold little attraction for the white practitioner, is not what it should be. Infant mortality is high among native children and the incidence of disease among them is great. Medical aid and assistance are rendered by mission doctors or by district surgeons, but such aid and assistance are quite inadequate for the large extent of area and the dense native population. The proposal has therefore been made that special physicians should be allocated to these native areas and that we should follow the lead of the French in West Africa, who have created an auxiliary medical service recruited from intelligent natives who are given a modified medical course and allowed to practice as auxiliary doctors. A somewhat similar policy has been followed in parts of the Dutch East Indies, particularly in Timor and Bali, where the "dokters djavi," educated at the School of Hygiene at Buitenzorg, act as assistant district surgeons. Such "auxiliars" are excused the lengthy preliminary training in the ancillary sciences; they are given a modified course in anatomy and physiology, and special attention is paid to teaching them practical medicine and surgery. Those in favor of this course being followed here point out that there is a dearth of European physicians, who cannot be induced to practice in the purely native areas; that native medical students cannot be educated locally to become registerable simply because public opinion does not permit such students working in hospitals where there are white patients and white nurses, and that if such native students are sent overseas they will probably become "detribalized." The protagonists of these proposals are largely those who are connected with native missions and who cannot make up their minds whether the native must be treated like a child or be allowed to work out his own salvation. The general opinion of the profession is against these proposals. The discussion at the congress plainly indicated that there was opposition to the views put forward, based on the denial of the arguments that it is necessary that there should be an inferior qualification for native practitioners, but perhaps much more on the undesirability of adding to the barriers that already separate the educated native from the educated European. Any native can enter as a medical student at one of our medical schools; as a matter of fact, natives have so entered and there is no proof whatever that their fellow students have received them unfavorably. The practical difficulty is not in the medical schools but in the hospitals, which are not under the control of the faculty and are governed largely by lay committees which will not permit, even if public opinion allowed them, a native senior student to attend white patients. The result of this is that native medical students leave in their third year and continue their clinical studies overseas, usually in Scotland. At present there are about a dozen native practitioners in South Africa, and their relations with their white colleagues are usually amicable, as their skill and professional knowledge are evidenced by their degrees. If they had "auxiliary qualification" such as they would obtain under the proposed scheme and had received their training in a native hospital, their status would be much lower, and they would have far less influence among their fellow natives than they have at present.

A government commission considered this matter some years ago and came to the conclusion that it could not recommend an "auxiliary scheme" of training for native medical students under special grants from the government. It advocated, rather, that promising native students should be given "medical scholarships" to enable them to obtain their medical training abroad. The missionaries are strongly against this scheme, as it removes the native student from their influence. So far as one can judge, these who favor the "auxiliary scheme" of training imagine that the native auxiliary doctors will confine their work to natives and will be wholly subservient to "Christian" influences while at the same time content to submit to tribal convention. One cannot understand, otherwise, why such stress is laid on the danger of "detribalizing" the native student who goes overseas for his diploma. To the logical mind it is unthinkable that a medical man, no matter where he is educated, can be anything else but "detribalized." The discussion on this matter threatened to become acrimonious at the congress but was dexterously sidetracked by a resolution to the effect that the matter should be left in the hands of the federal council of the association for consideration and report.

PROFESSIONAL PAPERS

Another subject for plenary discussion was "The Treatment of Parasitic Diseases," in which Dr. Annie Porter and Dr. Orenstein read opening papers. The discussion was instructive and lively, as most of those present had had experience with malaria, bilharzia, the dysenteries, lambliasis and giardiasis. In the surgical section a communication was made by Dr. Macgregor of Johannesburg, who has successfully treated cases of megacolon in children by excision of the sympathetic ganglions.

In the medical section Dr. Pringle opened the discussion on tuberculosis, from which it appeared that it is generally felt that the disease is much more widespread in this country than is supposed. Other papers were on the ketogenic diet in epilepsy, on the intra vitam diagnosis of pancreatic calculi, and on hyperpiesis. The congress was opened by the governor general, who in his address referred to the traditions of the profession and to the need for research work.

A Gold Medalist

The Medical Association of South Africa has awarded its first gold medal, for meritorious services rendered to the profession in South Africa, to Dr. William Darley-Hartley. He was born at Sheffield in 1854 and graduated from Guy's Hospital, London, in January, 1878. He is one of the few senior medical men in South Africa whose professional career dates back prior to the eighties. He came to South Africa as a military surgeon and took part in the Kaffir and Zulu wars of 1878-1879, being attached to the twenty-fourth regiment, the South Wales Borderers, a regiment which was almost decimated at the battle of Isanhlwana. In 1879 he started private practice at East London. After the Boer war he went to Europe and obtained his degrees of M.D. and M.R.C.P. London. On his return he devoted himself to medical politics, founded the *South African Medical Record,* now incorported with the *Medical Journal of South Africa,* and remained editor of this journal until his retirement in 1928, when he was elected emeritus editor and life honorary vice president of the Cape Western branch of the association. He has been a member of the medical council since 1904 and president of the council for some time. He has acted for many well known papers as war and local correspondent, besides being a frequent contributor to literary journals. The award of the gold medal to a man who has identified himself so closely with the interests of the profession and who is so generally popular and respected meets with unanimous approval.

Antityphoid Serum

Typhoid is one of our most prevalent diseases, and although its incidence has been much lowered by preventive inoculation and by Besredka's oral immunization method, it still occasions many deaths and leads to much economic wastage. For many years, experiments have been made in the direction of discovering a therapeutic antityphoid serum. Dr. Grasset, formerly of the Pasteur Institute and now medical serologist of the South Africa Institute for Medical Research at Johannesburg, has, in collaboration with Dr. Gory, perfected an antityphoid serum which seems to be efficacious and of practical value. Prophylactic vaccination must remain the best method of control of the disease, but the serum is of great usefulness in areas where such control, for local and other reasons, is difficult or impracticable. Especially in the native territories, where the disease is frequent, the serum is likely to be much used. It is the result of prolonged investigation of the antigenic relationship between European strains of *Bacillus typhosus* and strains of South African origin, and is used in injections of 40 cc. with intervals of twenty-four hours in between, three or four injections being usually sufficient to cause the temperature to drop. Drs. Grasset and Gory have published the results of their antityphoid serum therapy in the *Comptes rendus des séances de la Société de biologie* and now Dr. Grasset has published the results of his clinical trials with the South African serum. He reports that the use of the serum is followed by a rapid and consistently maintained improvement in the general condition and by disintoxication, with the disappearance of nervous and ataxic symptoms. The earlier the treatment is given in the course of the typhoid infection, the more rapid and marked are the results obtained. In the mixed and secondary infections, especially those in which there is pulmonary involvement, the serum seems to act especially well.

The "Interferential" Theory of Treatment of Disease

In an article in the *Wiener medizinische Wochenschrift* Dr. Mór Turnovszky of Targul Mures, Transylvania, Roumania, brought up the priority of the theory of interferential treatment of disease, a term which originated with him twenty-five years ago, when he published his observations in the same periodical, describing some concrete cases in which an incidental disease affecting the organism cured another already existing disease. He reported cases from his own practice. In one of these an epileptic patient was cured by an attack of typhoid. Another patient similarly got rid of chorea. Therefore a disease can be cured by means of another disease. He called this phenomenon an interference and suggested that other diseases could be cured by interferential diseases. His theory became the target of many attacks. In his book "The Cure of Epilepsy," Professor Sarbo called the interferential theory a true fantasmagoria. With the advent of the malaria therapy of dementia paralytica, as introduced by Professor Wagner-Jauregg in Vienna, the interferential method was rehabilitated, and Turnovszky found the time ripe to call the attention of the medical world to the fact that his interferential method is a reality. He does not claim priority over Wagner-Jauregg even in regard of treating a disease with another one, because similar experiments were made many decades ago. But he claims priority in regard to the denomination "interferential" treatment, an expression that he took from physics. It is taught that sound waves and electrical waves when crossing each other have various effects that baffle other waves. This phenomenon in physics is called interference, and he applied it to therapy in this sense.

Pistons That Stick in Syringes

Dr. Stephan Martonffy of Szilágysomlyó recommends a method of loosening pistons that have stuck in record syringes. In most cases the sticking of the piston is caused by the drying up of solutions containing albumin. It is a waste of time to boil the syringe or to warm it because boiling coagulates the albumin and it gets still more firm. It is futile also to attempt the use of acid, which coagulates the albumin and at the same time harms the syringe. The only practical method is to apply concentrated alkaline solutions. The alkali albuminate dissolves in the excess of potassium hydroxide and the sticking is stopped. The syringe is hung with cone down, or put in a tumbler, and the part above the piston is filled with a 10 to 20 per cent solution of sodium hydroxide and left for a day or two. The caustic gradually gets filtered into the narrow space between the piston and the glass, and when the first drop of caustic appears on the bottom of the tumbler the piston is released and can be easily pulled. The method is successful also in cases of rust. The application of caustic in the described way is important because thus it reaches most easily the surface that sticks. Immersing the whole syringe in the caustic solution is not practical because in this way the air bubbles that stick in the cone and between the piston and syringe wall prevent the caustic from reaching its destination.

New Bill on the Activity of Druggists and Pharmacists

It is an old complaint of Roumanian pharmacists that drug stores sell both official and nonofficial remedies; the druggists object to pharmacists selling toilet preparations, raw drugs and rubber goods. The druggist profession is not subject to any special schooling; druggists are regarded as simple merchants, and three years' apprenticeship in a drug store qualifies one to become a druggist. The new bill aims at special schooling and training from would-be druggists, and only those in possession of a certificate issued by the board of pharmacists are to be qualified for opening druggists' shops or acting in them as clerks. The new bill sharply outlines the list of those drugs which druggists are allowed to hold in stock. The draft allows them to sell proprietary medicines that do not contain poisons. It strictly forbids, however, preparation of a prescription. Roumanian druggists are ready to accept the new bill, but they want a paragraph added which forbids barbers to sell toilet preparations, face creams, hair pomades and lotions. The board of pharmacists protested against the insertion of the paragraph enacting that pharmacists should not sell perfumes, cosmetic preparations or rubber goods, and also against the enactment according to which druggists' shops may be open just like the chemists' shops, which may keep open on Sundays, and have to close two hours later than ordinary shops on week days. The government appointed a committee consisting of druggists and pharmacists to study Western conditions on the spot and to formulate the final draft of the bill after having the report of the committee.

BERLIN

(From Our Regular Correspondent)

Sept. 22, 1930.

Meeting of the German Pharmacologic Society

The session of the Deutsche pharmakologische Gesellschaft, held in Königsberg under the chairmanship of Schüller of Cologne, offered many new and interesting features. Starkenstein of Prague discussed the "Problems of Inflammation from the Pharmacologic Point of View." H. Freund of Münster presented the "Pharmacologic Problems of Febrile Disorders"; Storm of Leyden and Hansen of Heidelberg considered the "Field of Allergy," while Schulemann of Elberfeld offered a paper on the "Problems of the Reticulo-Endothelium and Its Functions." Of the other individual addresses only brief mention can be made: E. Poulsson of Oslo reported on researches from which it is evident that the reserve of vitamin A in the females of mammals is much greater than in the males. Seel of Hamburg was able to isolate vitamin A in an extremely pure form, which can be kept, however, only when dissolved in oil. Chemically, it is probably to be regarded as a labile oxidation stage of oxycholesterol, since artificial products of this kind, with similar action, can be prepared, and there is a great similarity between the two bodies as regards their physical behavior. Hildebrandt of Giessen reported that his investigations led to the conclusion that ephedrine acts; to be sure, on the peripheral vessels but its action is not in all respects equal to that of epinephrine. In his opinion the highly toxic effects of ephedrine on the heart exclude its use as a remedy in a state of collapse. According to O. Krayer of Berlin, changes in the frequency of the heart beat influence the volume of the output per minute much more than hitherto believed. The optimal range of frequency of the sufficient heart is rather extensive; the lower limit of the insufficient heart is shifted upward to a considerable extent. Antischkov of Leningrad reported on the dependence of the stimulability of the heart ventricle on the condition of the Keith-Flack sino-auricular node. Aschoff discussed the detailed structure of the system by which stimuli are conveyed to the heart. Duesberg of Berlin spoke on the mechanism of the action of liver diet, which was of great interest. In the regeneration of an anemia, the mode of decomposition of hemoglobin is of importance. With the formation of methemoglobin the regeneration process is accelerated and the hematin formation is lessened. In pernicious anemia, hematin is always present, if there are any blood decomposition products whatever; but in the crisis and at the beginning of the liver therapy, methemoglobin is demonstrable. This observation indicates that the substance active in the liver in pernicious anemia is a precursor of methemoglobin. A preliminary report has been published in the *Deutsche medizinische Wochenschrift* (number 38). Further details will be given later.

Attendants at the session got the impression that, after a period of conspicuous aloofness, pharmacology is again showing interest in questions of practical therapeutics, and it is the general opinion that it would be well if the observations of the clinic were brought out more fully in the session papers and particularly in the discussions that follow their presentation. Practical therapy, the inquiries into causal relations, and the rational methods of treatment would certainly score a gain, while the strictly scientific discussions would not suffer any abridgment. Many pharmacologists have a strong desire for such cooperation, and they have in recent years repeatedly given public expression to this desire.

The Prescription of Copernicus

Copernicus, who taught the world the order of the system of sun and planets now accepted, was originally a physician. In the old fortress in Frauenburg, East Prussia, where Copernicus spent many years, the Copernicus Room serves as a memorial of the great scientist, and in his portrait he is seen with his medical insigne, lilies-of-the-valley, which constituted his favorite drug. In a window seat of this room may be noted a copy of the only prescription of Copernicus that has been preserved. This document has been deciphered by Professor Eichholtz, the director of the Königsberg Pharmacologic Institute, and in the *Deutsche medizinische Wochenschrift* an account of his researches may be found. The prescription comprises twenty-one different substances, which were listed according to the rules of the art, doubtless with the aid of astrologic data. It begins with drugs of a vegetable nature, which, to some extent, are still used; for example, camomile and sandalwood. Copernicus interested himself in the growing in East Prussia of important foreign medicinal plants, in order to secure a supply for medical prescriptions. At the end of the list are the inorganic substances, which are influenced by the then so general belief in the therapeutic potency of precious stones, or jewels. Though we may read with a smile of prescribing emerald, sapphire, amber and corals, we will recall that gold and silver have returned to our armamentarium. The prescription, which was known before Copernicus, was handed down from one generation of physicians to the next, as is still the case. It was employed doubtless in gastric and intestinal disorders, and we have no reason to deny that it was effective in certain cases. We may assume that a physician such as Copernicus was perfectly able to recognize the therapeutic effects of his prescriptions. That may be seen from the fact that the lily-of-the-valley was his favorite medicinal plant. Of the drugs that he employed, that derived from the lily-of-the-valley was the most potent and, at the same time, the most dangerous. It could develop its therapeutic power only in the hands of a physician who, as Copernicus, was equally distinguished by his courage and his confidence. In any event, Copernicus may well be accorded a worthy place in the history of medicine.

Marriages

Scipio H. Africano to Miss Claire Adelaide Marola, both of Union City, N. J., September 20.

Borden Smith Veeder to Mrs. Eugene Henry Angert, both of St. Louis, September 15.

James H. D. Cunnie, Stonehurst, Pa., to Miss Rene Carpenter of Clifton, in September.

Henry C. Allen, Circleville, Ohio, to Mrs. Harriett Weldon of Columbus, August 27.

William J. Sullivan, St. Louis, to Miss Anna May Naylor, June 14.

Deaths

Ross Hall Skillern ⊕ Philadelphia; University of Pennsylvania School of Medicine, Philadelphia, 1897; professor of laryngology, Graduate School of Medicine of the University of Pennsylvania; professor of laryngology, Medico-Chirurgical College, 1912-1918; Chairman of the section on Laryngology, Otology and Rhinology, 1920-1921, of the American Medical Association; member and past president of the American Academy of Ophthalmology and Oto-Laryngology, and the American Laryngological, Rhinological and Otological Society; member of the American Laryngological Society, and the American College of Surgeons; member of the American Board of Otolaryngology since its inception; laryngologist to the Rush Hospital, 1900-1913; served during the World War; author of "The Accessory Sinuses of the Nose"; aged 54; died, September 20, of cerebral hemorrhage.

George Wallace Nott ⊕ Racine, Wis.; Rush Medical College, Chicago, 1896; member of the American College of Surgeons; formerly instructor of pathology at the Wisconsin College of Physicians and Surgeons, Milwaukee; on the staffs of St. Mary's and St. Luke's hospitals; aged 58; died suddenly, September 7, of heart disease.

Alfred James Grant, London, Ont., Canada; University of Western Ontario Medical School, London, 1901; member of the American College of Surgeons; assistant professor of surgery at his alma mater; chairman of the board of education; on the staff of St. Joseph's Hospital; aged 51; died, May 26, of heart disease.

Thomas Herbert Williams, Birmingham, Ala.; Birmingham Medical College, 1913; member of the Medical Association of the State of Alabama; on the staff of the South Highlands Infirmary; aged 40; died suddenly, August 5, of heart disease, while performing a cesarean operation.

Helen Arentsen Harbert, Kenosha, Wis.; Northwestern University Woman's Medical School, Chicago, 1891; aged 71; died, September 7, in St. Elizabeth's Hospital, of injuries received when she jumped from a third story window.

James R. Davey, Chicago; Chicago Medical College, 1887; member of the Illinois State Medical Society; for many years on the staff of the Illinois Charitable Eye and Ear Infirmary; aged 71; died, September 16, of angina pectoris.

William Russell Fargo, Baltimore; University of Maryland School of Medicine, Baltimore, 1929; aged 27; on the staff of the Union Memorial Hospital, where he died, September 13, as the result of an infection of the face.

Thomas S. K. Morton, Philadelphia; University of Pennsylvania School of Medicine, Philadelphia, 1885; formerly on the staff of the University Hospital; aged 65; died suddenly, September 8, in Princeton, N. J.

Frank Hopkins Hurd, Hiram, Ohio; Miami Medical College Cincinnati, 1872; member of the Ohio State Medical Association; aged 79; died, July 26, in the Cleveland Clinic Hospital, of cerebral abscess.

John Collison, Red Deer, Alta., Canada; McGill University Faculty of Medicine, Montreal, Que., 1901; formerly mayor and for many years member of the local school board; aged 57; died, May 15, in Vancouver.

Julius Edgar Duncan ⊕ North Wilkesboro, N. C.; University College of Medicine, Richmond, 1907; past president of the Wilkes County Medical Society; aged 55; died, August 15, of carcinoma of the rectum.

Robert L. Jump, Oakland, Calif.; Cooper Medical College, San Francisco, 1890; member of the California Medical Association; aged 65; died, June 16, of myocarditis and arteriosclerosis.

William Porteous McCowan, Winnipeg, Man., Canada; University of Toronto Faculty of Medicine, 1916; served during the World War; aged 39; died, May 16, of septic meningitis.

Marion Kirkland Scruggs, Itta Bena, Miss.; Medical College of the State of South Carolina, Charleston, 1881; aged 72; died in August, of cerebral hemorrhage and arteriosclerosis.

Benjamin Frank Murray, Boston; Tufts College Medical School, Boston, 1909; member of the Massachusetts Medical Society; aged 52; died, May 15, of bronchopneumonia.

Isaac Walter Umbel, Orient, Pa.; College of Physicians and Surgeons, Baltimore, 1906; aged 50; died, June 25, of a skull fracture received in an automobile accident.

Harry L. Miller, Indianapolis; American Health College, Cincinnati, 1886; aged 65; died, August 27, in the City Hospital, of general peritonitis and perforated gastric ulcer.

Leon Herbert Tombaugh ⊕ Waukegan, Ill.; Medical Department of Western Reserve University, Cleveland, 1877; aged 78; died, August 3, of myocarditis.

Julia Stringham Baright, East Northfield, Mass.; Chicago Homeopathic Medical College, 1889; aged 82; died suddenly, August 19, of cerebral hemorrhage.

Elias Smith Richardson, Evart, Mich.; University of Michigan Medical School, Ann Arbor, 1870; aged 88; died, August 16, of chronic myocarditis.

William Peyton Barton, Mount Juliet, Tenn.; Vanderbilt University School of Medicine, Nashville, 1882; aged 74; died, August 31, of cerebral hemorrhage.

John Austin Munson, Wawarsing, N. Y.; Medical Department of Columbia College, New York, 1883; aged 72; died, August 19, of chronic myocarditis.

Francis Xavier Beaulieu, Taunton, Mass.; Baltimore Medical College, 1900; member of the Massachusetts Medical Society; aged 51; died, June 13.

Robert Montgomery Houck, Vandalia, Ill.; Rush Medical College, Chicago, 1882; aged 72; died, August 28, in a hospital at Dowagiac, of diabetes mellitus.

S. P. Meredith, Mankato, Minn.; Hahnemann Medical College and Hospital, Chicago, 1882; aged 78; died, September 1, of hypertrophy of the prostate.

William F. Oliver, Arlington, Wash.; Medical Department of Butler University, Indianapolis, 1879; aged 71; died, August 24, of arteriosclerosis.

Winfred Carle Pike ⊕ Boston; Tufts College Medical School, Boston, 1900; aged 61; died, August 21, in Cape Elizabeth, Me., of angina pectoris.

William O. Cheeseman, Chicago; Hahnemann Medical College and Hospital, Chicago, 1884; aged 79; died, September 5, in Winnetka, Ill., of senility.

George Henry Pagels, Worthington, Ohio; Ohio Medical University, Columbus, 1898; aged 60; died, September 4, in Columbus, of heart disease.

James M. Hayes, Newport News, Va.; Howard University School of Medicine, Washington, D. C., 1914; aged 44; died, August 15, of encephalitis.

Charles B. Vigus, Eau Gallie, Fla.; Medical College of Indiana, Indianapolis, 1895; formerly mayor of Eau Gallie; aged 60; died, in August.

Oliver A. Price, Cincinnati; Louisville (Ky.) Medical College, 1890; aged 62; died, September 7, in the Deaconess Hospital, of cerebral edema.

Lucy A. Bannister, New York; Woman's Medical College of Pennsylvania, Philadelphia, 1902; aged 74; died, August 25, of coronary thrombosis.

Alexander F. MacLeod, Spokane, Wash.; University of Michigan Medical School, Ann Arbor, 1879; aged 82; died, June 30, of pneumonia.

Carter Braxton Dean, Waco, Mo.; Eclectic Medical Institute, Cincinnati, 1892; aged 90; was killed, August 8, in an automobile accident.

Thomas Russell Cooke, Atlanta, Ga.; Atlanta Medical College, 1867; aged 88; died, August 5, of cerebral hemorrhage and arteriosclerosis.

Harry B. Chritzman, Mercersburg, Pa.; Jefferson Medical College of Philadelphia, 1889; aged 62; died, March 24, 1930, of acute prostatitis.

William F. Matthews, Trenton, Tenn.; Vanderbilt University School of Medicine, Nashville, 1880; aged 75; died, July 29.

Francis James Bateman, Strathroy, Ont., Canada; Trinity Medical College, Toronto, 1888; died, April 12, of cardiovascular disease.

Benjamin Rosenbloom, Atlanta, Ga.; Atlanta School of Medicine, 1911; aged 45; died, July 29, of strangulated inguinal hernia.

Burnley Duke Tyler, Guthrie, Ky.; University of Nashville (Tenn.) Medical Department, 1894; aged 67; died, August 20.

Percy James Emerson, Sidney, B. C., Canada; University of Toronto Faculty of Medicine, 1911; aged 56; died, May 2.

Philip Henry Weber ⊕ Oakland, Calif.; Cooper Medical College, 1905; aged 49; died, July 7, at Yosemite.

Bureau of Investigation

THE PAVIA "CANCER CURE"

With a Brief Biographical Sketch of Its "Discoverer"

During the past year, editors of newspapers and magazines have received from one Burroughs F. Perry of 221 Shoreland Arcade, Miami, Fla., a piece of mimeographed publicity material headed, "Cancer and Goiter Cure Is Asserted." The statement is to the effect that one Charles Pavia, whom Perry describes as a "mental scientist of Miami," has discovered a wonderful cure for cancer and goiter! Further, according to Mr. Perry's material, the Pavia formula "feeds the cancer germs, satisfies it and destroys it by self satisfaction." One infers from this statement that cancer is caused by a germ and that this particular germ thinks so much of Mr. Pavia's remedy that when it gets the opportunity, it gorges itself to death!

The main exploiter of Pavia's remedy seems to be one R. B. Fisher, whose stationery announces him to be an attorney; he, too, does business from 221 Shoreland Arcade, Miami. Mr. Fisher has declared that he is the "Secretary-Treasurer of the corporation that is manufacturing his [Pavia's] remedies." According to Attorney Fisher, Pavia is not a "mental scientist" as stated by Perry, but a "medical scientist."

Mr. Fisher wrote to the American Medical Association, asking the Association's cooperation in testing out Mr. Pavia's "cancer and goiter remedy." Mr. Fisher was told that the Association received, on an average, one letter a week similar to his from persons who claimed to cure cancer and that if it attempted to undertake a scientific investigation of every one of these alleged cures, the Association would have time for nothing else and, besides, as experience has demonstrated, would be wasting its time in doing so. He was told, further, that the very fact that he classified Pavia's alleged remedy as a cure for both cancer and goiter indicated the lack of even an elementary knowledge of the problems involved. This letter so pained Mr. Fisher, who read into it the statement that the medical profession condemned all cancer remedies as worthless and not worthy of investigation, that he returned the letter written by the Bureau of Investigation, in order that it might be destroyed. The letter was returned in a registered envelope for which a return receipt was requested!

Later, Mr. Fisher sent to The Journal what he described as a biographical sketch of the life of Charles Pavia, "scientist of Miami." From this sketch, it appears that Charles Pavia was born in 1893 "on the east side of New York" of parents who came to the United States from Italy in 1883. As a child, Pavia sold newspapers and one of his customers was Alfred E. Smith. After leaving school, Pavia became a telegraph operator and, about that time, became interested in the development of a cure for cancer. Later, Pavia went to California, where he met Jack London. He then went to Alaska, where he met Rex Beach and Tex Rickard; returned to San Francisco, became a seaman on the Dollar Line, and went to Hawaii and Australia, met Captain Robert Dollar, who is said to have taken a liking to him. Once again Pavia came to San Francisco, where he is said to have gone into chemical and research work under "Professor William J. Thackeray, a well-known scientist, then in Oakland."

In 1918 Pavia returned to New Jersey to visit his parents and, while there, continued his experiments and developed a remedy that was applied to a friend of his, who "had a clot of blood forming on his head." In ninety days' time, "the head was entirely cured." Then a woman acquaintance with a "clabbed breast" was treated with Mr. Pavia's remedy and, as his biographical sketch says, "err [*sic!*] long the breast was entirely cured." During the influenza epidemic, "Mr. Pavia cured every case of that disease that came to his personal attention." He is said to have offered to Dr. Royal S. Copeland, at that time "Medical Director" of New York City, his formula, free of charge, if Dr. Copeland would use it in relieving the epidemic. But, alas, Dr. Copeland rejected the offer, because "the American Medical Association would not permit him to use any new-found remedy, unknown, and discovered by one not of the medical profession."

Disappointed by Dr. Copeland's attitude, Mr. Pavia kept his formula and experimented with it further and "found that his remedy cured not only influenza, La Grippe and pneumonia, but also burns, scalds, sores, carbuncles, boils, piles, rheumatism" —and what have you! Then Mr. Pavia went to Florida, where he bought considerable property and built a house and, as his financial condition improved, "he bought himself a handsome cruiser yacht." He was still further successful in the real estate field, making a fortune and buying still "another home in the Coconut Grove district" and continuing his experiments in materia medica.

Mr. Pavia was a good friend of William Jennings Bryan, says the sketch and "obtained many valuable ideas from Mr. Bryan in their discourses upon everloution [*sic!*] and the megnetic [*sic!*] powers of universal life." Another close friend of Mr. Pavia's, still quoting the sketch, was "'Uncle' Billy Witham of Atlanta, Georgia, the banker," as well as "Carl Fisher, the developer of Miami Beach" and "likewise the late James Allison."

By this time Mr. Pavia had developed a remedy "backed by proven and unquestioned tests" that would cure cancer, as well as another remedy "for tumors." But, about this time, the Florida real estate boom collapsed and the hurricane that visited Miami in 1926 destroyed his "laboratory equipment." As a result, Pavia, it is said, lost the fortune he once had. Mr. Pavia still has his "cures" for various conditions, however, and is at present experimenting with a "capsule for the internal treatment of cancer, also another remedy which he hopes will aid tuberculosis victims."

So much for the biographical sketch of Mr. Pavia. Later publicity matter sent out by attorney Fisher, secretary and treasurer of the Pavia corporation, includes an elaborate testimonial for Pavia's "cancer cure," credited to L. D. Rogers of Chicago. Readers of this department of The Journal will remember L. D. Rogers and his "Auto-Hemic Serum" quackery that was dealt with in detail some years ago.

A year ago, Pavia and Fisher called on Dr. Charles D. Cleghorn, president of the Dade County (Miami, Fla.) Medical Association, with the request that he would check up on certain cases of patients that had been treated with the Pavia remedy. Dr. Cleghorn did check up on three cases, on which he reports as follows:

> "Case 1.—White female, aged 42, recurrent carcinoma of cervix after operation and radiation. Reported incurable. After a month's application of salve, condition was increased in severity and size.
>
> "Case 2.—White female, aged 48, carcinoma of cervix of two years' duration, one radium radiation. No change after seven weeks' application.
>
> "Case 3.—White male, aged 50, inoperable carcinoma of lower face. No treatment until February, 1929, but two years' duration. Deep x-ray therapy for three months with little result. Steady loss of flesh and strength and increased discharge and hemorrhage following Pavia remedy." [Dr. Cleghorn reported, later, that this patient "proceeded to an early death."]

In June, 1930, the Miami Industrial Board was requested to appoint a committee to take up an investigation of the "cure." After a short review, they refused to appoint such a committee.

What the remedy itself is, we do not know. Dr. Cleghorn states that the description of the formula, as given him, was "vegetable oils, camphor, menthol and turpentine in a base of animal fats." The chemists of the A. M. A. Chemical Laboratory reported that a cursory examination of a specimen of this remedy showed it to be a brownish-yellow ointment with a terebinthinate odor, indicating the presence of turpentine, menthol and camphor. There was practically no ash, and qualitative tests indicated the absence of heavy metals (arsenic, zinc, etc.), alkaline earth metals, salicylates and alkaloids.

It thus appears from information at hand that Mr. Pavia's "cancer cure" differs from the average "cancer cure" paste in that it is not a caustic substance. From the directions that go with the preparation, the patient is instructed to dissolve a tablespoonful of common salt, or epsom salt, in a half-pint of water, bathe the malignant area, and let it dry without wiping; then apply the paste and change the substance at least three times daily. The patient is also told to abstain from meats, but in another paragraph is notified that he may eat beef liver, lamb and spring fowl! While it would appear that the preparation was intended primarily for external application, the instructions also state that in cases of cancer of the stomach, rectum or uterus, "the salve may be applied with a tampon."

In closing, it is but fair to state that the exploitation of this remedy does not seem to have the crude and heartless commercial taint that is to be found in such cancer-cure fakes as the Hoxsey, the Tilton, the Koch, or some of the other widely-exploited remedies in this field. It may well be that Mr. Pavia is sincere. However, a worthless cancer remedy sincerely exploited may prove just as fatal (by deferring scientific treatment beyond the curative stage) as the crudest of cancer cure swindles.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted on request.

TETANUS AFTER GUNSHOT WOUND

To the Editor:—I recently cared for a man who had been shot in the buttocks with two buckshot. These shot perforated the body of the ileum and passed on into the abdominal cavity, where they perforated the bowel in about eighteen places. I saw the patient about eight hours (?) after he was shot. A laparotomy was performed and the perforations were closed. One shot was located and removed when it was discovered during the repair. Owing to the precarious condition of the patient, tetanus antitoxin was not given. An uneventful recovery with profuse drainage up to the tenth day was made. On the tenth day, after about two hours of headache, the patient was seized with a typical tetanic convulsion. The head held back rigidly, the eyes wide open and staring straight ahead, or pulling upward, bloodshot, and the jaw rigid. With great effort he acknowledged questions with slight forced movements. He later told us all the questions we asked. The treatment was 5,000 units of tetanus antitoxin, five minutes after the convulsion started; 40,000 units intravenously fifteen minutes after the convulsion started; 53,000 units intramuscularly twenty minutes after the convulsion started, and then 20,000 units every hour intramuscularly for five hours, or 100,000 units, making a total of 193,000 units. Five hours after the onset of the convulsions, the patient was free from all tetanic contraction. No history of epilepsy was found. A history of a skull injury five years previously was found. No convulsions followed. Some of my contemporaries maintain that this could not be tetanus or the recovery could not have been so rapid. I have seen two cases of tetanus previous to this, and I maintain it was a typical tetanus, with a typical history and incubation period, and was a recovery following the immediate use of the antitoxin. May I have your discussion or opinion?

E. J. Ball, M.D., Nekoosa, Wis.

Answer.—The type of wound involving the intestine ten days before the onset of the convulsions fits in with the predisposing factors of tetanus. Treatment was well carried out and it is quite probable that recovery may be credited to the prompt and energetic administration of antitoxin. However, cases of tetanus which develop after the first week have a fairly good prognosis with antitoxin treatment.

While it is known that antitoxin has no effect on the toxin that has entered into contact with the nervous system, the history of this case is not at all incompatible with tetanus. It illustrates the importance of huge doses of antitoxin as early after the onset of symptoms as possible.

Local surgical treatment for drainage of pus pockets and the correction of conditions favoring the development of anaerobic organisms should be done both in the prophylaxis and the treatment of tetanus.

RETICULOCYTES IN BLOOD

To the Editor:—Please inform me as to the proper way to determine and detect the number of reticulocytes in the blood. How are they recognized?

A. W. Patterson, M.D., Fonda, Iowa.

Answer.—The reticulated structure of the red cells is not observed with ordinary stains but requires "vital stains" to bring out this detail. There are several methods which have been suggested for the detection and enumeration of reticulocytes. The following is sufficient for ordinary work:

A drop of a solution of brilliant cresyl blue (0.3 per cent) in 95 per cent alcohol (filtered) is allowed to dry on a cover glass. The drop is spread evenly over the cover glass with a glass rod, and the alcohol evaporates leaving a thin film of the dried stain deposited on the glass. Large numbers of cover glasses can be prepared for future use as the dried stain does not deteriorate. A drop of blood is placed on a clean slide and the cover glass is lowered on to it. If the glass has been thoroughly cleaned and there is no precipitate of stain, the blood will spread out evenly and the stain will diffuse through the preparation immediately.

If no permanent record is desired, the cover glass may be ringed with petrolatum or melted paraffin and examined under the microscope. This preparation keeps for only a few hours. In cases in which regeneration in response to treatment is of interest, it is often an advantage to prepare permanent preparations for record. This can be done by modifying the technic described.

A permanent preparation can be made if, after the cover glass has been lowered on the slide, it is pulled off the slide by a quick lateral tug and allowed to dry in the air. Schilling has introduced a detail in the last part of the method which, if properly carried out, gives a satisfactory preparation. Instead of allowing the cover glass to dry immediately it is placed in a damp chamber (petri dish lined with moistened filter paper) for from five to ten minutes and then dried in the air. The cover glass can now be stained in the routine manner for staining blood smears.

The reticular material stains blue (basophilic) and is easily recognized in the pink stained red corpuscles. The appearance of reticulocytes varies and a blue precipitate of different patterns is seen, depending on the concentration of the so-called reticulum in the cells.

The reticulated red cells encountered in from 500 to 1,000 red cells are counted and the percentage is calculated. The preparation must be sufficiently thin and even to facilitate this count. In normal blood the number of reticulocytes has been estimated at 2 per cent.

PRISM-REFRACTOMETER

To the Editor:—Enclosed please find circular on a prism-refractometer. I would appreciate information about this instrument.

F. N. Knapp, M.D., Duluth, Minn.

Answer.—This instrument is not new, having been on the market for at least five years. It is just as accurate as any of the other refractometers that have appeared during the past twenty years and is probably a little simpler to use. The personal equation of the operator plays a definite part as in all similar instruments, and the results are fairly comparable to a rapid test-case manifest refraction. However, the advertisement is incorrect in stating that "it is possible with it to obtain reliable results without employing atropine." The accommodation of the patient is not relaxed in the slightest during the examination with this instrument; consequently, the refraction is no more accurate than any other refraction without cycloplegia.

TREATMENT OF RENAL CALCULI

To the Editor:—Will you kindly outline the most approved treatment for renal calculi in a man 38 years of age?

M.D., Alabama.

Answer.—There is no single method of treatment that under all conditions may be designed as superior to other treatments. The selection of therapeutic intervention depends on the peculiarities of each instance. As leading working points may be considered the intensity of the suffering of the patient, the frequency of renal colics and the objective symptoms developing as to morphologic and functional renal disturbances. Pronounced symptoms originating with concretions within the kidney parenchyma form a strict indication for operative removal.

In some instances of pelvic calculi an attempt at flushing out the stones may be indicated and occasionally such a procedure may be successful. This intervention may be justified if the concoction or concretions are of moderate size and if the contours of their roentgen shadows are smooth and regular. Very large stones and stones of irregular and rough surface are not a favorable object for such attempts. It also has to be considered whether their mobilization does not inflict traumatism to the structures more severe than their operative removal.

The cystoscopic removal of stones is attempted by ureteral catheterization and the injection of some lubricant. The therapeutic value of various drugs to be taken orally in order to promote the evacuation of concretions is rather doubtful. The flushing may be repeated if the catheterization is not followed by severe reaction.

Star shaped concretions, especially if one branch extends into the *ureteropelvic junction, cannot be the object of cystoscopic* removal. Pronounced deformation of the renal pelvis, copious hematuria and the appearance of functional disturbances of the renal parenchyma form a strict indication for operative removal. This indication is more accentuated if every renal attack is accompanied by general malaise, vomiting and disturbances in the lower intestinal tract.

The modern tendency is to regulate or remove all abnormalities. For the application of this general rule to renal concretions it also has to be considered that the operative removal of renal conditions properly executed is particularly without danger of life and furnishes satisfactory immediate results. There is just as little guarantee against recurrence in the cystoscopic as in the operative removal.

Spinal anesthesia, gridiron exposure of the kidney and pelvotomy permit the operative removal of renal concretions under the most favorable prospects.

POSSIBLE ANEURYSM IN CRANIUM

To the Editor:—A white woman, aged 49, married, seen June 16, had had a sudden diplopia two days before while she was working about the house. This was her only symptom for about an hour. Then she had a sudden excruciating pain in and around the right eye. Rapidly the pain extended over the entire head and into the back of her neck. Another physician had seen her at the onset of the attack. When I first saw her she complained of diplopia, ptosis of the right eyelid, excruciating pain in and around the right eye, severe headache, and pains in her neck. She had had typhoid at 21 but no other severe illnesses. She was in a slight car accident in 1918. About May 25, 1930, while hoeing in the garden, the patient had a similar sudden pain in the right eye and was totally blind. She lay down for about an hour and felt perfectly well. About June 6, while papering a ceiling, she had a similar attack of pain in the right eye, diplopia and headache for about an hour, but no blindness. Examination, June 16, revealed complete ptosis of the right lid, the right pupil widely dilated and fixed, the right eye deviated outward and somewhat downward and inability to move the right eye—in other words, a total ophthalmoplegia. The blood pressure was: systolic, 180; diastolic, 100. Kernig's sign was positive. Neurologic examination was otherwise negative. The remainder of the physical examination was negative except for a small adenomatous goiter and a loud systolic murmur over the entire precordium. The patient was conscious and cooperative. Several hypodermic injections of morphine were required to control the pain. Spinal puncture done the next day showed bloody fluid under considerably increased pressure. The eye pains and headache were completely relieved for two days after spinal puncture. Two days after the first visit she was found to have developed an auricular fibrillation, which responded to digitalis medication. Laboratory examination showed the urine normal and spinal fluid and blood Wassermann reactions negative. Now, five weeks after the onset of the present attack, she still has a total ophthalmoplegia, occasional pains in the right eye and a loud systolic murmur over the entire precordium, without other neurologic symptoms. Kindly give opinion as to the most probable lesion and prognosis. Please omit name.

M.D., Minnesota.

Answer.—The abrupt onset and the presence of blood in the spinal fluid make it most probable that the lesion is of vascular origin, possibly a hemorrhage from an aneurysm. Its location must be within the cranium or at least there must be a communication with the subarachnoid space. All three attacks have involved the right eye only and have affected not only the motor nerves but also the optic nerve in one attack and the sensory nerves. This renders it probable that the lesion is located somewhere near the optic foramen, though one would expect to find some proptosis from pressure on the veins. This symptom is not mentioned. If this diagnosis is correct, while it is possible that there may be recovery from the palsies due to damage to the motor nerves, there is always a serious danger of a recurrence of the bleeding with possibly a fatal result. It would be wise to have the patient seen by a neurosurgeon for study as to diagnosis and the possibility of surgical intervention with a view to ligating an aneurysm if present.

RADIUM AND ROENTGEN RAY IN UTERINE CANCER

To the Editor:—What is the percentage of cures of inoperable cancer of the uterus by the use of radium or roentgen rays?

A. V. Bou, M.D., San Lorenzo, Porto Rico.

Answer.—Bowing and Fricke reviewed 1,094 cases of carcinoma of the cervix treated with radium at the Mayo Clinic from 1915 to 1924. They were able to follow up 1,001 cases for a number of years, and of the 549 cases traced, which were considered inoperable, 21.49 per cent were classified as five year cures.

Healy reviewed the cases of carcinoma of the cervix treated by irradiation at the Memorial Hospital, New York, in 1922 and 1923; of the 161 patients admitted in the advanced stage, 23 per cent were alive at the end of five years. Healy grouped these cases from the histologic standpoint of the degree of anaplasia in the biopsy specimens into the adult cell type, the plexiform, and the anaplastic. These groups corresponded closely to three degrees of potential malignancy, as well as to the grades of radiosensitivity. The adult cell type of carcinoma is resistant to radiation and the anaplastic type is highly radiosensitive, while the plexiform type occupies an intermediate position. The percentage of cures among the adult cell type was only 4, while among the anaplastic carcinomas the percentage of cures was 42.

Among 58 patients treated with radium by Harrold, after a five year period 31 per cent were still living and had no sign of recurrence. Ward refers to a study by Heyman of the results of surgical and radium treatment in carcinoma of the cervix at the Radium-Hemmet in Stockholm. Heyman combined the cases from twenty surgical clinics and seventeen radiologic clinics, leaving out all doubtful statistics and not deducting intercurrent deaths or cases not traced. His standard in this study was the usual five year cure and, of the total cases treated, including operable, inoperable and borderline cases, there was 16.3 per cent of cures following radiologic treatment. Obviously, these figures cannot be directly compared with the preceding ones. The percentage of cures among the operable and borderline cases in Heyman's survey was 34.9.

HYPERGLYCEMIA

To the Editor:—Will you please tell me what are the criteria for differentiating hyperglycemia of diabetes mellitus from that of chronic nephritis, or cite me to the literature bearing on the point? Please withhold name.

M.D., North Carolina.

Answer.—It is not always easy to differentiate a hyperglycemia of diabetes mellitus from that of chronic nephritis. The history is of considerable importance, as a patient with diabetes who has reached the stage of secondary nephritis will usually give a characteristic history and will usually also show glycosuria. On the other hand, the patient with nephritis will not give a diabetic history and will not show glycosuria. In case of doubt the reaction to an increase of carbohydrate load may settle the point. The hyperglycemia due to diabetes will almost invariably respond to excessive carbohydrate intake with glycosuria, while the nephritic will not.

On the other hand, there is a certain group of elderly arteriosclerotic patients with glycosuria and hyperglycemia. There is still considerable dispute as to whether these patients are truly diabetic or not, but from a practical point of view their reaction to excessive carbohydrate load is of importance in differential diagnosis.

SIGNIFICANCE OF BLOOD PRESSURE DETERMINATIONS

To the Editor:—What is the significance of a high diastolic pressure in (*a*) low systolic; (*b*) normal systolic; (*c*) high systolic? Please omit name.

M.D., New York.

Answer.—The diastolic pressure is assumed to vary with changes in the peripheral resistance, and a high diastolic pressure to indicate an increased peripheral resistance. The peripheral resistance may be increased by vasoconstrictive changes in the peripheral vessels, by increased tonus, or by anatomic changes in the vessels. Where there is a high diastolic pressure and a comparatively low systolic pressure, it might be assumed that there is an increased peripheral resistance with a *relatively* small volume output from the heart, the result in some cases of insufficient heart action. Such a condition does obtain in the later stages of cases in which there has been a high systolic pressure, and the heart is failing. It is also seen in cases which for the time at least appear to be doing well. The high diastolic pressure is nevertheless ominous and significant. The second class, with the normal systolic pressure, probably belongs in the same category as those with a low systolic pressure. The cases showing high diastolic and high systolic pressures represent the condition normally found in hypertensive kidney and vascular disease, in which there is an increased peripheral resistance due to vasoconstrictor changes in the arterioles, or increased tonus in the larger vessels, with a strongly acting heart muscle forcing a normal, or in some cases an increased, volume output through the constricted vessels.

TREATMENT OF POSTOPERATIVE ADHESIONS

To the Editor:—Is there anything that can be done for adhesions after abdominal operations (three were done on my patient although I believe unnecessarily) aside from morphine? Please omit name.

M.D., New York.

Answer.—There is a general feeling among American surgeons that operations for relief of symptoms ascribable to abdominal adhesions are ill advised. It is assumed that separation of adhesions will be accompanied by the creation of raw surfaces and followed by the formation of fresh adhesion bands.

In general, operations for relief of adhesions yield a high percentage of satisfactory results, provided the adhesions are located in the lower part of the abdomen. The operation must be performed gently, patiently and with painstaking care. Deliberate inspection and careful manipulation of the adherent surfaces reveal natural lines of cleavage where the tissues may be separated by blunt dissection without creating fresh raw surfaces. The use of a rubber pack rather than gauze packing, blunt dissection in preference to cutting, and gentle separation in contrast with tearing, are all essential features in the technic. Methods available for the covering of raw surfaces, the employment of omental grafts, and other technical features in the detail of these most difficult operations cannot be discussed adequately in an abbreviated reply.

EOSINOPHILIA AND ASTHMA

To the Editor:—What is the relationship between eosinophilia and asthma? I read the other day that when a diagnosis of asthma is in doubt the finding of more than 2 per cent eosinophils confirmed the diagnosis. Please omit name.

M.D., Michigan.

Answer.—Eosinophilia occurs in most cases of true allergic bronchial asthma. Percentages vary—rarely less than 2 and frequently from 8 to 12 or even higher. It is an important point in arriving at the diagnosis. However, some cases show no increase in eosinophils. Eosinophilia is found not only in the blood but also in allergic lesions elsewhere, such as in the mucosa of allergic (hyperesthetic) rhinitis.

THERAPEUTICS OF IRON—USE OF ARSPHENAMINES AND SODIUM THIOSULPHATE

To the Editor:—1. What is the comparative value of iron by injection and by mouth? What is the best iron preparation for use hypodermically, indications for such use and efficacy of this medication? 2. Can neoarsphenamine and sulpharsphenamine be dissolved in a solution of sodium thiosulphate in using these arsenicals intravenously and does such a procedure ward off the ill effects of these drugs in susceptible persons? Kindly omit name.

M.D., New York.

Answer.—1. There is no advantage to the administration of iron by injection, excepting in cases of gastric intolerance. For this purpose, iron and ammonium citrate, 1 cc. of 10 per cent solution, is perhaps the most commonly used form. Though efficient, this method of administration is too painful and too liable to be followed by local and systemic reactions to be employed for any excepting unusual conditions.

2. Neoarsphenamine can be dissolved in sodium thiosulphate solution; and it is claimed by K. Hubschmann (*Urol. & Cutan. Rev.* **34**:91 [Feb.] 1930), on entirely insufficient experimental and clinical evidence, that this combination lessens the toxicity without impairing the activity of the arsenical. In general, it is considered to be much better to give the arsphenamine preparations alone, that is, without admixture with other substances, owing to the possibility of undesired chemical reactions or contamination.

JACKSON'S MEMBRANE

To the Editor:—I would like the definition, possible etiology, and treatment of Jackson's membrane. Please omit name.

M.D., New York.

Answer.—Jackson's membrane is a term usually applied to a broad filmy band or membrane covering the anterior wall of the cecum and first part of the ascending colon. It sometimes includes the appendix. There are usually numerous blood vessels giving it a congested appearance.

The colon is often bound to the parietal peritoneum, which sometimes produces kinking or obstruction to it or to the appendix. Dr. Jabez N. Jackson has emphasized the importance of these bands as a cause of local subacute or chronic symptoms, such as pain, tenderness, constipation, mucous colitis, meteorism, gastric symptoms and neurasthenia.

It is doubtful whether this contention is true except in instances wherein definite kinking or obstruction may be demonstrated by roentgenography or at operation. Consequently, the treatment of this condition is ordinarily unnecessary unless there is evidence of kinking or obstruction.

When treatment is indicated it should consist of division of the adhesions and peritonization of all denuded surfaces, if possible. In addition, the appendix should be removed and the abdomen thoroughly explored for other pathologic changes.

It is thought by some authors that these membranes which occur also in other locations on the colon and in the abdomen are due to a low grade infection in that region, while other writers believe that they are congenital in origin. The exact cause is not known.

ORAL USE OF OVARIAN PRODUCTS IN MENOPAUSE NOT ESTABLISHED

To the Editor:—I should like to know the present status of the oral use of ovarian products in the treatment of neurotic manifestations of menopause.

O. M. Unger, M.D., Providence, R. I.

Answer.—Rational as ovarian therapy may theoretically appear to be in some conditions, the actual results are rarely striking and often nil to the careful observer. Extensive clinical experience has failed to establish the value of the desiccated preparations administered orally. The Council on Pharmacy and Chemistry has omitted all desiccated ovary preparations for oral administration because long extended clinical use has failed to demonstrate the efficacy of the marketed brands of such preparations.

Thyroid extract in small amount, e. g., one-half grain (0.03 Gm.) once or twice daily, may help in the treatment of neurotic manifestations of the menopause. Most of these patients are benefited by outdoor life, free elimination, and abstinence from coffee.

OSTEOMYELITIS OF THE PATELLA

To the Editor:—I have a case of osteomyelitis of the patella in a boy, aged 14 years, due to a puncture wound. The condition was preceded by a large abscess over the knee and at present there is a suppurating cavity in the patella about 1 cm. in diameter. Does the treatment and the reaction to treatment differ from osteomyelitis in any other bone? Apparently the joint beneath is not involved.

M.D., Virgina.

Answer.—There are several local conditions that may modify the treatment of osteomyelitis of the patella. The first to be considered is the probable involvement of the prepatellar bursa. Owing to the history of a large abscess over the knee joint, the bursa was probably in the original suppurative process. The bursa was probably involved first, and the osteomyelitis secondary. At the operation, this sac should be dissected out; otherwise, the discharge may continue.

The local osteomyelitis of the patella should be treated, in general, as any osteomyelitis. However, one should be extremely careful in saucerizing and removing the irregular walls of the cavity in the patella to avoid opening into the knee joint, since this might result in at least ankylosis, if sepsis is avoided.

If careful saucerizing of the cavity and removal of the bursa with wide open drainage is done, prompt granulation of the wound should be expected.

HAMMOND'S MIXTURE

To the Editor:—Would you be so kind as to send me the formula of "Hammond's mixture"? I enclose stamped envelop for reply. Should you publish this, please omit my name.

M.D., Iowa.

Answer.—The formula for "Hammond's mixture" is:

Pepsin (scale)	12
Wood charcoal U. S. P.	24
Potassium bromide	64
Water to make	250

Pepsin is seldom indicated because the gastric juice usually contains sufficient pepsin for gastric digestion. Charcoal has long been administered in cases of flatulence, the prescribers evidently losing sight of the fact that when thoroughly wet it loses its property of absorbing gases. In view of these two facts, it would appear that the prescription would likely do no more than would a solution of potassium bromide itself.

FORMATION OF ALCOHOL IN THE BODY

To the Editor:—Permit me to add to your answer to Dr. A. D. Bush of Decatur, Ga., on formation of alcohol in body, in The Journal, August 23. The existence of alcohol in normal tissues was found also by Ford, Landsberg, Reach, Voeltz and Dietrich, Taylor and Schweisheimer (Ford: *New York M. J.* **15**:561, 1872. Reach: *Biochem. Ztschr.* **3**:326, 1907. Voeltz and Dietrich: *Biochem. Ztschr.* **40**:15, 1912. Taylor: *J. Biol. Chem.* **15**:217, 1913. Schweisheimer: *Deutsches Arch. f. klin. Med.* **109**:271, 1913). Dr. Bush will find this information in one of the textbooks from which he taught pharmacology (Sollmann's Manual of Pharmacology, ed. 2, p. 651).

Aaron Levine, M.D., Cincinnati.

South Carolina: Columbia, Nov. 11, 1930. Sec., Dr. A. Earle Boozer, 505 Saluda Ave., Columbia, S. C.

Texas: Waco, Nov. 18-20, 1930. Sec., Dr. T. J. Crowe, 918-19 Mercantile Bank Bldg., Dallas, Texas.

West Virginia: Morgantown, Nov. 20, 1930. Sec., Dr. W. T. Henshaw, Charleston, W. Va.

ADDITIONAL HOSPITALS AND LABORATORIES APPROVED

The Council on Medical Education and Hospitals of the American Medical Association has given its approval to the following hospitals and laboratories since the publication of the last previous list in The Journal, July 26:

Hospitals Approved for Intern Training:

Holy Cross Hospital, Chicago.
Illinois Masonic Hospital, Chicago.
Silver Cross Hospital, Joliet, Ill.
Charles S. Wilson Memorial Hospital, Johnson City, N. Y.
Troy Hospital, Troy, N. Y.

The following hospitals, which had been approved for interns for a number of years and were omitted from the list printed in The Journal, Aug. 16, 1930, are again fully approved for interns:

Providence Hospital, Washington, D. C.
Bethesda Hospital, Cincinnati.
Christ Hospital, Cincinnati.
Jewish Hospital, Cincinnati.
St. Mary Hospital, Cincinnati.

Hospitals Approved for Residencies in Specialties:

Peoria Municipal Tuberculosis Sanitarium, Peoria, Ill.
Hurley Hospital, Flint, Mich.
Albany Hospital, Albany, N. Y.
Kings County Hospital, Brooklyn.
Kingston Avenue Hospital, Brooklyn.
Buffalo State Hospital, Buffalo.

Pathologists Conducting Approved Clinical Laboratories:

Thomas Cajigas, M.D., director, Clinical Pathological Laboratory, Washington, D. C.
W. J. Muzzy, M.D., director, El Reno Sanitarium Laboratory, El Reno, Okla.

Ohio July Reciprocity Report

Dr. H. M. Platter, secretary of the State Medical Board of Ohio, reports 43 candidates licensed by reciprocity with other states and 2 by the endorsement of National Board of Medical Examiners credentials at a meeting held July 8, 1930. The following colleges were represented:

College LICENSED BY RECIPROCITY	Year Grad.	Reciprocity with
University of Arkansas School of Medicine	(1929)	Arkansas
George Washington University Medical School	(1928)	Maryland
Howard University School of Medicine	(1929)	Virginia
Emory University School of Medicine	(1928)	Georgia
Northwestern University Medical School	(1929)	W. Virginia
Indiana University School of Medicine	(1929)	Indiana
State University of Iowa College of Medicine	(1926)	Iowa
University of Kansas School of M	[illegible]	Kansas
University of Louisville School	[illegible]	Kentucky
University of Maryland School o (1928) (1929) Maryland	[illegible]	W. Virginia
Detroit College of Medicine and Surgery	(1917)	Michigan
U. of Michigan M. S.	(1903) (1924) (1926) (1927) (1929, 2)	Michigan
St. Louis University School of Medicine (1929, 2) Missouri	(1929)	Louisiana
Columbia University College of Phys. and Surgs.	(1916)	New York
University of Buffalo School of Medicine	(1929, 2)	New York
Hahnemann Med. College and Hosp. of Philadelphia (1926) Kentucky, (1929) Indiana	(1928)	Penna.
Jefferson Medical College	(1926)	Penna.
Temple University School of Medicine	(1918)	W. Virginia
University of Pennsylvania School of Medicine	(1927)	Penna.
Medical College of the State of South Carolina	(1929)	S. Carolina
Meharry Medical College (1928, 2) Tennessee	(1922) Alabama, (1924)	Virginia
University of Toronto Faculty of Medicine	(1926)	Michigan
University of Western Ontario Medical School	(1913)	Tennessee

College ENDORSEMENT OF CREDENTIALS	Year Grad.	Endorsement of
University of Pennsylvania School of Medicine	(1924)	N. B. M. Ex.
University of Jena Faculty of Medicine	(1919)	N. B. M. Ex.

Indiana Reciprocity Certificates

Dr. W. R. Davidson, secretary of the Board of Registration and Examination of Indiana, reports 25 permanent certificates and 9 temporary permits issued to physicians through reciprocity with other states from Jan. 1 to April 2, 1930. The following colleges were represented:

College PERMANENT CERTIFICATES	Year Grad.	Reciprocity with
Georgetown University School of Medicine	(1899)	Iowa
Hahnemann Medical College and Hospital, Chicago	(1906)	Kansas
Loyola University School of Medicine	(1929)	Michigan
Northwestern Univ. Med. School	(1927) Michigan, (1928)	Illinois
Rush Medical College (1927, 2) (1928, 2) (1929, 2) Illinois	(1925)	Minnesota
University of Illinois College of Medicine	(1929)	Illinois
State University of Iowa College of Medicine	(1923)	Michigan
University of Louisville School of Medicine	(1928, 2)	Kentucky
Johns Hopkins University School of Medicine	(1921)	Ohio
University of Michigan Medical School	(1928)	Michigan
St. Louis University School of Medicine	(1926)	Missouri
Starling Medical College	(1880)	Ohio
Western Reserve University School of Medicine	(1923)	Ohio
Jefferson Medical College	(1912)	Penna.
Woman's Medical College of Pennsylvania	(1924)	Ohio
Meharry Medical College	(1913)	Tennessee
University of Tennessee College of Medicine	(1910)	Tennessee

College TEMPORARY PERMITS	Year Grad.	Reciprocity with
College of Physicians and Surgeons, Los Angeles	(1918)	California
Howard University School of Medicine	(1928)	Dist. Colum.
Northwestern University Medical School	(1923)	Iowa
Rush Medical College	(1928) (1929)	Illinois
University of Illinois College of Medicine	(1928)	Illinois
University of Minnesota Medical School	(1925)	Minnesota
Albany Medical College	(1908)	New York
University of Budapest Faculty of Medicine	(1915)	Illinois

Colorado April Examination

Dr. William W. Williams, secretary of the Board of Medical Examiners of Colorado, reports the examination held at Denver, April 1, 1930. The examination covered 8 subjects and included 80 questions. An average of 75 per cent was required to pass. Three candidates were examined and passed. The following colleges were represented:

College PASSED	Year Grad.	Per Cent
University of Illinois College of Medicine	(1929)	87.2*
Harvard University Medical School	(1929)	81.5
University of Pennsylvania School of Medicine	(1928)	89.1

Dr. Williams also reports the endorsement of credentials of 11 physicians at the meeting held April 1, 1930. The following colleges were represented:

College ENDORSEMENT OF CREDENTIALS	Year Grad.	Endorsement of
Hering Medical College	(1899)	Illinois
University of Illinois College of Medicine (1922) Illinois	(1912)	Wyoming
State Univ. of Iowa College of Med.	(1923) Utah, (1927)	Iowa
Kansas Medical College	(1906)	Kansas
Johns Hopkins University Medical School	(1923)	Maryland
University Medical College of Kansas City, Mo.	(1903)	Kansas
University of Nebraska Coll. of Med.	(1928) Kansas, (1929)	Nebraska
Vanderbilt University School of Medicine	(1924)	Arkansas

* This candidate has received his four year certificate and will receive an M.D. degree on completion of one year's internship in a hospital.

Book Notices

Pernicious Anemia. By Leybourne Stanley Patrick Davidson, B.A., M.D., F.R.C.P.E., Lecturer in Systematic and in Clinical Medicine in the University of Edinburgh, and George Lovell Gulland, C.M.G., LL.D., M.D., Consulting Physician to the Royal Infirmary, Edinburgh. With appendix on Dietetic Treatment by Ruth Pybus, Sister Dietitian, Royal Infirmary, Edinburgh. With introduction by Lawrence D. Thompson, M.D., Assistant Professor of Clinical Medicine, Washington University School of Medicine. Cloth. Price, $8.50. Pp. 293, with 30 illustrations. St. Louis: C. V. Mosby Company, 1930.

Recent investigations of fundamental importance dealing with pernicious anemia were doubtless the inspiration for this monograph. The authors have considered critically all of the important contributions concerning this disease, from the earliest description to the recent classic investigations of Peabody, Minot, Murphy, Cohn and Castle. All aspects of the disease are discussed comprehensively, including the historical development of knowledge, the physiology of blood formation and destruction, the pathology and etiology of the disease, and various clinical considerations dealing with the diagnosis, prognosis and treatment. Of unusual interest are the views of the authors concerning the etiology of the disease. They are in accord with the growing opinion in this country as they accept Cohnheim's original belief that the abnormal formation of blood is the primary factor in the disease and reject Hunter's hypothesis, which emphasizes hemolysis as the essential feature. They do not accept completely, however, the observations of Castle, which appear to suggest strongly that the underlying cause of pernicious anemia is an inability of the gastric mucosa to produce a substance which, acting in protein, elaborates an unknown factor controlling the maturation of the red blood cells. The chapter devoted to diagnosis is well presented and, in addition to discussing the usual diseases from which the pernicious anemia must be differentiated, properly emphasizes the confusion that may arise between it and aleukemic leukemia. The section on treatment is well written, and especial attention is given to the use of liver or liver extract, which the authors consider gives entirely satisfactory results without any subsidiary treatment. It does not seem logical, however, as they suggest, to omit the liver therapy temporarily and administer iron. Nor is there convincing evidence to indicate that dilute hydrochloric acid is essential to the treatment. The importance of infection is discussed, as it is known that when such a condition is present the action of liver is less efficient. This applies chiefly to acute infections with a febrile reaction rather than to "sepsis" in the sense of a chronic abscess of the teeth. Blood transfusion is recommended, as it is an emergency measure which maintains life until liver therapy becomes effective. It is difficult to agree with the authors that the combination of transfusion and liver therapy produces a bone marrow stimulation far greater than either procedure alone as evidenced by a greater reticulocyte rise. The latter depends on the initial level of the red blood cell count and it is possible in some instances that transfusions just prior to treatment with liver may diminish the height of the reticulocyte curve. In general, it may be said that the book is thoughtfully and carefully written by observers who are thoroughly familiar with the subject. It is to be commended to those who are especially interested in diseases of the blood as well as to students and practicing physicians.

Physiologie pathologique, chirurgicale; inflammations, effets des traumatismes, Réparation des plaies, greffes, maladies des os, des articulations, des vaisseaux et des nerfs. Par R. Leriche, professeur de clinique chirurgicale à la Faculté de Strasbourg, et A. Policard, professeur d'histologie à la Faculté de Lyon. Paper. Price, 26 francs. Pp. 212. Paris: Masson & Cie, 1930.

This comprises a series of ten brief essays on the pathologic physiology of bones, joints, tendons, muscles, bursae, connective tissue, blood vessels, peripheral nerves, and transplants (grafts) of these tissues. The changes in the subcutaneous tissue caused by trauma and seen in sterile and septic inflammation are reviewed. The discussion of the pathologic physiology of bones and joints is of course based on the authors' humoral theory of ossification and bone absorption. "Anything that produces an active hyperemia in bone could be the origin of a process which some day results in arthritis deformans. Traumatism, infection, malformations, none of these are direct causes. Trauma acts on bone by causing a vasomotor disturbance. If there is infection the bacteria or their toxins do not affect directly the synovia or bone, but only through causing a vascular disturbance; there being a local vasomotor disturbance usually in hyperemia. Once such processes are begun, they progress of themselves." The discussion of the pathologic physiology of peripheral nerves and vessels includes Leriche's recent and well known experimental work on the effect of sympathetic nerve operations on vascular tone. In the pathogenesis of inflammatory edema, a "nervous vasoparietal" factor is emphasized. The final essay, dealing with tissue transplants, is a brief review of the generally accepted principles on the subject. The authors state in the preface that their treatise is an expression of personal opinion and is the result of fifteen years of observation and experimentation. Much that is said, however, coincides with the generally accepted views on the subject. The book is written in the clear concise style typical of the best French works. There are no illustrations nor is there a bibliography. While not intended for students, the work may be profitably read by them for a correlation of certain phases of physiology and surgery. For the surgeon, this book offers an attractive and brief scientific discussion of many problems confronting him in his daily work and presents numerous suggestions for further experimental work.

A Hemato-Respiratory Study of 101 Consecutive Cases of Stammering. By Max Trumper. A thesis presented to the faculty of the graduate school in partial fulfillment of the requirements for the degree of Doctor of Philosophy. Paper. Price, $1. Pp. 72, with illustrations. Philadelphia, 1928.

This details a research into the conditions of breathing and of blood in 103 stammerers, of whom 80 were adults. About half of the adults had low vital capacity (the greatest amount of air that can be expired after a maximum inspiration). One third were shallow breathers. "The cases exhibited a correlation between the type of breathing and the red cell count and hemoglobin content." Shallow breathing was compensated by a high red count and high hemoglobin. In some cases, deep breathing compensated for low vital capacity. "When the compensation was adequate, the red cell count and hemoglobin were normal, where incomplete the erythrocytes and hemoglobin were increased." In other cases in which depth of breathing was normal, the blood observations also were normal. Such studies should eventually disclose either a physical correspondence or a difference between the stammerer and the nonstammerer. In this paper a similar study of nonstammerers is not provided for such comparison. Moreover, since confirmed stammerers were studied, whether the abnormal observations, when present, should be reckoned on the side of cause or of effect is not clear. The study is a worthy one and should be continued and extended.

La radiothérapie pénétrante. Par MM. Ledoux-Lebard, chargé de cours de radiologie clinique à la Faculté de médecine de Paris, et Étienne Piot, électroradiologiste des Hôpitaux de Paris. Paper. Price, 15 francs. Paris: Gauthier-Villars & Cie, 1930.

This is a delightfully readable and valuable summary of the field of high voltage roentgen therapy. The authors call attention to the fact that high voltage roentgen therapy can be administered with a radiation that is only slightly penetrating and, inversely, that penetrating filtered radiation may be utilized in superficial radiotherapy. He defines high voltage roentgen therapy as that given by utilizing a tension of 200 kilovolts and a filtration of 1 mm. copper with a minimum effective wavelength of 0.17 angstrom unit. To deliver to an organ deeply situated a sufficient radiation to obtain therapeutic action without damaging the skin or intervening organs is the purpose of high voltage roentgen therapy, but this object cannot be truly and completely realized except by utilizing "penetrating" roentgen therapy. The authors propose the classification agreed to by the Commission of Therapeutics of the Society of Medical Radiology of France: for superficial therapy, 50 kilovolts, a 3 mm. aluminum filter, and an effective wavelength of 0.35 angstrom unit; for therapy requiring medium penetration, 150 kilovolts, 0.05 mm. of copper filter, and an effective wavelength of 0.15 angstrom unit; for penetrating roentgen therapy, 200 kilovolts, 1 mm. of copper or zinc filter, and an effective wavelength of 0.10 angstrom unit. There are chapters on the physiologic and biologic bases, the technic of roentgen therapy and the clinical indications in cancerous and noncancerous diseases, the dose being always expressed in roentgens, the international unit of x-ray dosage. The r universally adopted in Germany and in this country is equivalent to 2.5 r of the French standard.

CLINICAL NUTRITION AND FEEDING IN INFANCY AND CHILDHOOD. By *J. Newton Kugelmass, M.D., Ph.D., Sc.D.*, Associate Attending Pediatrician, Fifth Avenue Hospital. Cloth. Price, $6. Pp. 345, with 37 illustrations. Philadelphia: J. B. Lippincott Company, 1930.

As stated in its preface, this book is intended to supply the general practitioner with information concerning the etiology, diagnosis and treatment of the problems of pediatrics involving nutrition. The first four chapters deal with the normal energy and foodstuff requirements, properties of the foodstuffs, prenatal nutrition, normal breast and artificial feeding, and normal child feeding. In considering the physiology of nutrition, the author reviews various theories and quotes the most recent advances in physiologic chemistry and metabolism. The space given to normal artificial feeding is scanty. There is a short chapter on the alimentary diseases. The nutritional diseases of infancy are designated as acute intestinal indigestion and acute intestinal intoxication. Treatment of these conditions is stressed and is in general sound, although the use of cathartics and a starvation period as long as twenty-four or forty-eight hours might be questioned in some pediatric circles. The chapter on deficiency diseases includes discussions on rickets, scurvy, beriberi, xerophthalmia and acrodynia. Malnutrition and marasmus are included in this chapter, as is dental caries. The chapter on metabolic diseases includes detailed and technical discussions of the acid-base mechanism and alkalosis. These discussions are rather technical and will probably prove too much for the average general practitioner. The diets for obesity and diabetes mellitus are excellent. The nephritides are considered under the general heading of metabolic diseases, but they would perhaps best deserve a separate chapter. Tetany is considered separate from rickets, and the ketogenic dietary treatment of epilepsy is given ample space. The ketogenic diet, as the most rational treatment for chorea, does not meet with universal approbation. The chapter on blood diseases is quite complete; however, the statement that ultraviolet radiation from natural or artificial sources increases the red cells and hemoglobin and prolongs the life of the erythrocytes has not been substantiated experimentally. Hemophilia is generally considered a purely familial disease and is probably uninfluenced by diet. The chapter on diet in infectious diseases is brief and to the point, and the book concludes with tables of various food values. The book is well illustrated throughout and food tables for the various conditions are included in each chapter for ready reference.

ÉTUDES RADIOLOGIQUES SUR LE POUMON ET LE MÉDIASTIN. Par M. de Abreu, de l'Institut Brésilien des sciences et de l'Académie de medecine de Rio. Paper. Price, 50 francs. Pp. 200, with illustrations. Paris: Masson & Cie, 1930.

Here is an attempt to reach more accurate radiologic diagnosis and prognosis by application of mathematical formulas to roentgenography of the chest. The first part deals with roentgenography of the lung. It describes methods for finding the square area of lung lesions and gives a scale of shades determined by the density of shadows cast by normal organs in the thorax. Mathematical formulas are then given by means of which the volume of the lesions may be estimated from their square area and the density as indicated by the shade of the lesions. The author emphasizes the value of serial examinations for prognosis. The second part deals with roentgenography of the mediastinum. The author advances the theory that differences in depth of shadow cast by various mediastinal organs are not due to different densities of the organs, as has been commonly accepted. He asserts that the depth of shadow and its size as well as its definition are determined entirely by the geometric relations existing in the mediastinum and particularly by the proximity of the mediastinal surfaces of the lungs which afford a contrasting surface by means of which definition is obtained with different degrees of clarity according to the angles at which the rays penetrate. He states that he has substantiated this theory by a series of wax models of the mediastinal space. These models were homogeneous throughout; yet films showed virtually the same shadows as are obtained in a normal mediastinum. The third part is a discussion of the possibility of obtaining mathematical knowledge of the blood vessels in the mediastinum and attempts to determine accurately enlargement of the vessels, including the breadth and length of the aortic arch. The book is profusely illustrated with roentgenograms and diagrams showing the geometry of the chest. Numerous equations are given. While some will not agree with the theory ascribing all differences in density in mediastinal pictures to geometric relations alone, there is no doubt that the author has made progress toward greater accuracy in roentgenologic diagnosis and prognosis and the reader cannot fail to be impressed by the bringing together of clinical, pathologic and roentgenologic as well as mathematical data.

LES ALIÉNÉS ET LES CORRECTIONNAIRES À SAINT-LAZARE AU XVII^{e} ET AU XVIII^{e} SIÈCLES. *Par le Docteur Jacques Vié*, médecin des Asiles. Paper. Pp. 251. Paris: Félix Alcan, 1930.

Saint Lazare began in 1124 as a hospital for lepers and later under Vincent de Paul it became the center of the congregation of the mission but continued to receive patients. This book is a study of the great monastery and hospital from 1632 to 1789, during which time it served as an asylum for the mentally diseased and as a house of correction. The methods of placement, classification and treatment are studied in detail. The book should be of much interest to those interested in the history of institutional care of mentally diseased and abnormal persons.

PHYSIOLOGY AND BIOCHEMISTRY OF BACTERIA. Vol. II: Effects of *Environment upon Microörganisms*. *By R. E. Buchanan, Ph.D.*, Professor of Bacteriology and Bacteriologist of the Iowa Agricultural Experiment Station, Iowa State College, and Ellis I. Fulmer, Ph.D., Professor of Biophysical Chemistry, Department of Chemistry, Iowa State College. Cloth. Price, $7.50. Pp. 709. Baltimore: Williams & Wilkins Company, 1930.

PHYSIOLOGY AND BIOCHEMISTRY OF BACTERIA. Volume III: Effects of Microörganisms upon Environment. Fermentative and Other Changes *Produced*. *By R. E. Buchanan, Ph.D., Professor of Bacteriology* and Bacteriologist of the Iowa Agricultural Experiment Station, Iowa State College, and Ellis I Fulmer, Ph.D., Professor of Biophysical Chemistry, Department of Chemistry, Iowa State College. Cloth. Price, $7.50. Pp. 575. Baltimore: Williams & Wilkins Company, 1930.

These two volumes present an extensive compilation of the literature relating to the physiology of micro-organisms. Volume II deals with the effect of the physical and chemical environment. It presents first of all certain laws relating to rates of reaction. This is followed by sections on the effects of temperature on morphology, metabolism and the various phases of growth and death rates of micro-organisms, the effects of rays and emanations, mechanical pressure, osmotic pressure, surface tension and other physical environments. The section dealing with the chemical environment takes up in turn the effects of such an environment on growth and death rates, the subject of disinfection and disinfectants, the influence of various inorganic compounds and their ions, and the effect of both non-nitrogenous and nitrogenous organic compounds. Volume III covers the subjects of physiologic interrelationships among micro-organisms, enzymes, and the chemical changes produced by micro-organisms in inorganic compounds, in non-nitrogenous organic compounds and in the nitrogenous organic compounds. The scope of these two volumes is enormous and embraces the more fundamental aspects of a large share of the field of microbiology. There is much material collected here which has not heretofore been brought together and the work will therefore serve as a useful and convenient or, indeed, indispensable reference. While it is recognized that any large compilation presents problems in the arrangement of material, it would seem that all of the information on the utilization of the sugars and alcohols, for example, might have been brought together in a section in one volume rather than divided between a section in each of the two volumes. The same holds true for other non-nitrogenous and the nitrogenous organic compounds. To gain a complete picture of the reports on the uses of these substances and their decomposition products, one must consult both volumes. It is to be regretted, too, that the publishers have not printed the headings of subsections in more conspicuous type. Such points, however, are overshadowed by the really enormous amount of work brought together and summarized with full bibliographies and index. Since the progress of a science is often well served by pausing to review disclosures of the past, bacteriologists will be distinctly indebted to the authors for the production of these volumes.

Stereoskopischer Atlas der Äusseren Erkrankungen des Auges nach farbigen Photographien fur Studium und Ärztliche Fortbildung mit begleitendem Text. Lieferung 2. Von Karl Wessely, Professor in München. Boards. Price, 12 marks. Ten plates (11-20). Munich: J. F. Bergmann, 1930.

This atlas is published in ten sections, and the second group of ten pictures which has just appeared includes two which demonstrate the author's treatment of serpiginous ulcer of the cornea. All the photographs maintain the high standard set in the first series, and the next instalment is anticipated with pleasure and certain profit.

Medicolegal

When Damages Are Payable for Fright

(Baltimore & Ohio R. Co. v. McBride (U. S.), 36 Fed. (2d) 841)

McBride was an engineer on one of the defendant's trains. While he was so engaged, a plug blew out of the engine boiler. He was badly scalded and was compelled to jump from the cab, landing between the rails of an adjacent track. He suffered multiple injuries, including a fracture of the left leg. As he lay thus disabled, he was further shocked and terrified by the approach of a through train on the track on which he lay and by calls to stop it. The engine was in fact stopped only a few feet from him. McBride brought action to recover damages, and from a judgment in his favor the railroad company appealed to the U. S. Circuit Court of Appeals, Sixth Circuit.

On behalf of the railroad company it was contended that no causal relation had been shown between the blowing out of the plug and the subsequent fright or nervous shock of the injured engineer; that no damages could be recovered for such unforeseen and unforeseeable results as were claimed to have occurred in the present case; and that the fright and nervous shock being disconnected from the original accident called for the application of the doctrine that no recovery can be had for nervous shock unaccompanied by physical injury.

The legal rule, however, that requires that the accident for which the plaintiff is responsible shall be the proximate cause of the defendant's injuries does not require that the defendant must have been able to foresee the precise injuries which in fact resulted, but only to foresee that results of a generally injurious nature might be anticipated from the negligent act or omission. The question was, said the court, "Did the facts constitute a continuous succession of events, so linked together as to make a natural whole, or was there some new and independent cause intervening between the wrong and the injury?" Viewed in the light of all of the circumstances of the case, severe nervous shock seems not only prospectively probable as a result of the railroad company's negligence, but rather as certain to follow. There was no intervening efficient cause and no break in the chain of causal connection. The final result was in a very true sense foreseeable.

There was no ground for the application of the doctrine that damage from nervous shock, unattended by physical injury, is too remote to support a recovery of damages. Where both the physical injury and the nervous shock are proximately caused by the same act of negligence, there is no necessity that the shock result exclusively from the physical injury. Each forms a part of the natural and indivisible result, and the fact that the plaintiff has suffered physical injury as a part of the aggregate of the attending results precludes the defense that the connection between the negligent cause and the resulting nervous shock is too remote for legal contemplation.

The judgment of trial court in favor of the injured engineer was affirmed.

Public and Private Hospitals Distinguished

(Brister v. Leflore County (Miss.), 125 So. 816)

In July, 1916, the King's Daughters and Sons Circle and the city of Greenwood and the county of Leflore entered into an agreement for the erection of a hospital and for its joint control and management. Later, in order to enlarge the hospital, the voters of the county of Leflore authorized the issuance of bonds to raise $30,000. A taxpayer brought suit to prevent the bond issue, alleging that it would be invalid, because section 183 of the constitution, 1890, forbids any county, city, town or other municipal corporation from making an appropriation or loaning its credit in aid of any railroad or other corporation or association. From a judgment against him, the taxpayer appealed to the Supreme Court of Mississippi, Division B.

If, said the Supreme Court, the corporation sought to be aided is a public corporation, it is not covered by the provisions of the constitution stated; if it is a private corporation, the constitutional inhibition is clear and distinct. The question is, therefore, Is the King's Daughters and Sons Circle a private corporation within the meaning of the constitutional provision stated? Public corporations, the Supreme Court of New York has said, are the instrumentalities of the state (or of a subdivision thereof), founded and owned by it in the public interest, supported (in whole or in part) by public funds, and governed by managers deriving their authority from the state (or from a subdivision thereof). *Van Campen* v. *Olean General Hospital*, 210 App. Div. 204, 205 N. Y. S. 554, 555. The rule is, said the court:

> A corporation therefore is not a public corporation merely because it is founded for a public charity. . . . While an institution founded . . . for purposes of general charity such as a hospital for the poor, the sick, the disabled or the insane may well be regarded as a public institution, yet in the sense of the law a far more limited, as well as a more exact, meaning is intended by a public institution or corporation. 14 Corpus Juris 73.

The ultimate test is this: Is the continuity of the corporation, and its control and management, under the power of the public through public agents who are accountable to the government?

The legislative act authorizing the proposed bond issue provides that the expenditure of the money "shall be under the control of the board of supervisors." When the money was expended, however, it would go into buildings. These, being real estate, would merge into the title now held by the King's Daughters and Sons Circle, and the money would be represented by property the title to which would be in the hands of a private corporation. The stockholders and board of directors of that corporation, being under no legal control by the state or county, would have the full legal power to sell and convey such real estate and to divert it from the public uses for which it was intended. The conclusion is inescapable, therefore, that the appropriation proposed would be an appropriation to a private corporation and in clear violation of the constitution. The fact that the constitution authorizes the legislature to provide for the care of the indigent sick in hospitals does not help the matter. The property of one person may not be taken and given over to another as a pure donation or gratuity, and such taking and giving is no more permissible when it is done under the guise of taxation than it would be if it were done by direct force or violence.

There is, however, said the court, no legal reason why a county, a municipality and a private person or corporation may not, on a joint three-party arrangement, acquire and operate a public hospital, if the arrangement is such that the majority control remains in the public, through responsible public agents or managers, or if the services to be rendered are covered by an obligatory contract so specific in its provisions that it can be enforced in a court of competent jurisdiction by the public authorities. There must, however, be such a just and reasonable relation between the services to be rendered and the payments made as to avoid the charge that a part of the payment made or to be made out of public funds is in fact only a donation or gratuity.

The decision of the trial court was reversed and the cause remanded.

Foreign Body in Bronchus Following Tonsillectomy

(Emery v. Fisher (Me.), 148 Atl. 677)

The defendant, Fisher, had been employed to remove the plaintiff's diseased tonsils. While ether was being administered preparatory to the operation, the patient became cyanotic. The defendant-physician, who was in an adjoining room preparing to perform the operation, was hurriedly called. He used a mouth gag to force the patient's mouth open, to enable him to breathe. Soon after the patient resumed breathing, it was discovered that a rubber tip was missing from the end of the mouth gag. Search for it was unsuccessful. The defendant suspected that it had slipped off, or been pulled off by contact with the patient's teeth, and had been either swallowed or, what seemed less likely, drawn into a bronchus. In the opinion of the defendant, however, good judgment and good surgical practice demanded that, notwithstanding the loss of the rubber tip and regardless of its place of lodgment, the contemplated operation be performed, and he therefore removed the patient's tonsils. After a further search had been made for the rubber tip, without success, the defendant suggested to the patient's attending physician that the patient's stools be carefully examined during the next few days to determine whether or not the tip had passed into the digestive tract, and that the patient be watched for the development of a cough, indicating the presence of the rubber tip in a bronchus. A cough did develop, a roentgenogram was taken, and the tip was discovered and removed. The patient thereupon brought suit against the physician, Fisher, who had performed the tonsillectomy, in the Supreme Judicial Court, York County. The issue submitted to the jury was whether the tip found its resting place in the patient's bronchus by reason of the negligence of the defendant or of an accident not attributable to lack of due care on his part. The patient contended, too, that after the physician-defendant, when about to operate, found that the rubber tip had disappeared and realized the possibility of its lodgment in a bronchus, he should have taken steps immediately to locate it and, having so located it, he should have removed it at once, instead of proceeding with the operation. After a verdict in favor of the patient, the physician appealed to the Supreme Judicial Court of Maine.

It was strongly urged by counsel for the patient that the tip did not become detached from the mouth gag during the emergency caused by the cyanotic condition of the patient, but a fair reading of the record, said the appellate court, established the truth of the defendant's contention that it was lost at that time. There was no evidence that the mouth gag was unfit for use. Assuming, then, that the rubber tip was lost during the emergency, no act of negligence, either of omission or commission, on the part of the defendant caused the injury of which the patient complained. Whether, after having failed to locate the lost rubber tip and suspecting that it might have lodged in a bronchus, the physician should have taken further steps to locate it and, having located it in a bronchus, should have removed it at once, instead of proceeding with the tonsillectomy, was distinctly a matter of judgment for the operating physician. All that was eventually done must necessarily have been done if the tonsil operation had been deferred. The only difference would have been the removal of the rubber tip a few days earlier. The patient, however, suffered no harm from the delay and was subjected to no appreciable damage. All of the experts summoned by the patient united in commending the course which the defendant pursued.

The verdict of the jury apparently rested on no more secure foundation than the facts that the rubber tip found its way into the plaintiff's bronchus and that the plaintiff was thereby subjected to considerable expense and to the annoyance of another operation. Surgeons, however, neither warrant against accidents nor guarantee the results of their operations. Their liability is limited within certain clearly defined lines; a surgeon contracts that he possesses ordinary skill, that he will use ordinary care, and that he will exercise his best judgment in the application of his skill to the case which he undertakes. No claim was made that the defendant in the present case was not skilled in his profession. There was no evidence to warrant the assumption that he did not use ordinary care and exercise his best judgment in the application of his skill to the case. An unfortunate result, however, arising from an accident, excusable under the circumstances, was made the basis of a finding of negligence. While the Supreme Judicial Court does not review questions of fact, yet when a conclusion of fact is without support in evidence, a question of law is raised, which the court may properly consider. To justify the court in sustaining a verdict, "there must be substantial evidence in support of the verdict—evidence that is reasonable and coherent, and so consistent with the circumstances and probabilities in the case as to raise a fair presumption of its truth." A verdict of a jury on matters of fact cannot be the basis of a judgment where there is no evidence to support it, or when the jury had made inferences contrary to all reason and logic. The appeal of the physician-defendant, therefore, from the verdict in favor of the patient was sustained.

Workmen's Compensation Acts: Detachment of Retina Not Due to Accident.—The claimant, a carpenter, fell from a stepladder early in May, 1928, while engaged in his work. He continued to work that day and for about three weeks thereafter, although his eye was bloodshot after the accident and there was some pain and blurring of vision. Then, May 23, he became suddenly blind in his right eye. The state industrial board awarded compensation, and the employer appealed. The difficulty, said the Supreme Court of New York, Appellate Division, Third Department, is to identify the blindness with the accident. Such identification must depend on medical testimony. Eminent oculists have been called, however, but none is able to state with reasonable certainty that the fall from the stepladder was the cause of the claimant's condition. Some of these oculists have eliminated practically every other cause, but for some unexplained reason they hesitate to express a definite opinion that the origin of the detached retina was in the accident. They say it is "possible," but go no further. In the absence of other evidence leading to a reasonable conclusion, this is not sufficient. The finding of the state industrial board that the detachment of the retina arose naturally and unavoidably from the accident is therefore not sustained by the evidence. The award was reversed and the claim remitted to the board.—*Wood v. W. E. Joyce Co., Inc., et al. (N. Y.), 239 N. Y. S. 110.*

Society Proceedings

COMING MEETINGS

American Academy of Ophthalmology and Otolaryngology, Chicago, October 27-31. Dr. W. P. Wherry, Medical Arts Building, Omaha, Secretary.

American Academy of Physical Therapy, Boston, October 22-24. Dr. Thomas L. Smyth, 111 North Eighth Street, Allentown, Pennsylvania, Secretary.

American Association of Railway Surgeons, Chicago, November 5-7. Dr. Louis J. Mitchell, 29 East Madison Street, Chicago, Secretary.

American College of Surgeons, Philadelphia, October 13-17. Dr. Franklin H. Martin, 40 East Erie Street, Chicago, Director-General.

American Hospital Association, New Orleans, October 20-24. Dr. Bert W. Caldwell, 18 East Division Street, Chicago, Executive Secretary.

American Public Health Association, Fort Worth, Texas, October 27-31. Mr. Homer N. Calver, 370 Seventh Avenue, New York, Executive Secretary.

Association of American Medical Colleges, Denver, October 14-16. Dr. Fred C. Zapffe, 25 East Washington Street, Chicago, Secretary.

Central States Pediatric Society, Memphis, Tenn., November 7-8. Dr. A. H. Parmelee, 310 South Michigan Boulevard, Chicago, Secretary.

Delaware, Medical Society of, Dover, Oct. 14-15. Dr. W. O. La Motte, Medical Arts Building, Wilmington, Secretary.

Interstate Postgraduate Medical Association of North America, Minneapolis, October 20-24. Dr. W. B. Peck, 82 Stephenson Street, Freeport, Ill., Managing Director.

Medical and Surgical Association of the Southwest, El Paso, Texas, November 6-8. Dr. W. Warner Watkins, Box 1587, Phoenix, Ariz., Secretary.

Mississippi Valley Conference on Tuberculosis, Rockford, Ill., October 14-16. Dr. Robinson Bosworth, Box 1005, Rockford, Secretary.

Missouri Valley, Medical Society of the, Des Moines, Iowa, October 15-17. Dr. Joseph D. McCarthy, 107 South Seventeenth Street, Omaha, Secretary.

Radiological Society of North America, Los Angeles, December 1-5. Dr. I. S. Trostler, 25 East Washington Street, Chicago, Secretary.

Southern Medical Association, Louisville, Ky., November 11-14. Mr. C. P. Loranz, Empire Building, Birmingham, Ala., Secretary.

Virginia, Medical Society of, Norfolk, October 21-23. Miss Agnes V. Edwards, 104½ West Grace Street, Richmond, Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to The Journal in continental United States and Canada for a period of three days. Issues of periodicals are kept on file for a period of five years only. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending, but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Plateau R-T in Case of Lobar Pneumonia. M. C. Shearer, New York. —p. 801.

Bundle-Branch Block with Short P-R Interval in Healthy Young People Prone to Paroxysmal Tachycardia.—Eleven cases are reported by Wolff et al. of an unusual cardiac mechanism, heretofore undescribed as such, consisting of functional bundle-branch block and abnormally short P-R interval, occurring mostly in otherwise healthy young people with paroxysms of tachycardia or of auricular fibrillation. From a study of eleven cases they conclude that: (*a*) Aberrant ventricular complexes of the type generally recognized as indicating bundle-branch block may occur in healthy people with normal hearts. (*b*) Vagal stimulation is capable of altering markedly the form of the ventricular complex and may be responsible for the occurrence of complete bundle-branch block curves in apparently normal hearts at normal rates of beating. (*c*) Vagal stimulation may shorten markedly the P-R interval without the production of auriculoventricular nodal rhythm, and without dislocating the auricular pacemaker. (*d*) In the group of cases reported, paroxysmal tachycardia and auricular fibrillation are associated with the nervous control of the heart. (*e*) The recognition of functional bundle-branch block is of considerable practical importance. The combination of intraventricular block with abnormally short P-R interval, interchangeable with normal ventricular complexes with longer P-R interval (reversion spontaneous or following exercise or atropinization) in healthy young people with paroxysmal tachycardia (or auricular fibrillation) is distinctive. (*f*) This mechanism is apparently not indicative of disease of the heart.

Course and Prognosis in Coronary Thrombosis.—The records of 287 cases of coronary thrombosis have been studied by Conner and Holt with respect to the clinical course of the disease from the time of the first attack. Approximately 85 per cent of these cases were found in men and 15 per cent in women. An analysis of the age incidence at the time of the first attack discloses the fact that in one third of all the cases the first attack occurred before the fifty-first year and in three fourths of the cases before the sixty-first year. It seems evident, therefore, that coronary thrombosis must be regarded as essentially a disease of early middle life rather than of elderly life as it is usually held to be. Evidence of an arterial hypertension was found in 34 per cent of the cases; of syphilis in 14 per cent, and of diabetes in 10 per cent. Of the 287 patients studied, 117 are known to be living and 142 to have died. The immediate mortality in the first attack was 16.2 per cent. Of 117 patients who recovered satisfactorily from the first attack, 75 per cent were in good health at the end of one year; 56 per cent at the end of two years; 21 per cent at five years, and 3.4 per cent at ten years. One patient remained in good health for seventeen years and died in a second attack eighteen years after the first. In 62 per cent of the patients the first attack supervened, without antecedent circulatory symptoms, in persons who had no reason to doubt the integrity of the heart. A single attack only of thrombosis is recorded in 67 per cent of all the patients; two attacks occurred in 24 per cent; three attacks in 4 per cent, and from four to seven attacks in 5 per cent. Of the patients having but a single attack, one half are living and one third are in good health. Among the patients having two or more attacks, the time interval between the first and the second attack was less than one year in half of the cases and in the other half varied from one to eighteen years. Signs of arterial embolism appeared forty-nine times among forty-two patients. Twenty-eight of the embolic attacks involved the systemic arteries and twenty-one the pulmonary artery. Although the immediate mortality in attacks of coronary thrombosis is higher when the initial symptoms are severe than when they are mild, yet almost one third of the patients who recovered from the attack had symptoms of very severe character.

Excitatory Process Observed in Exposed Human Heart.—A study of the arrival of the excitation process at a number of points on the surface of the human heart with reference to the beginning of R in lead II was made by Barker et al. It was found that the order of excitation differs in some respects from that found by Lewis and Rothschild in the dog. The earliest points were on the anterior surface of the right ventricle near the atrioventricular border. Their results suggest that the conducting tracts in the right ventricle of man may differ from those of the dog. The curves produced by stimulation of various points on the surface of the human heart were recorded in the three standard leads taken simultaneously. These curves indicate that: (*a*) Ventricular premature contractions of right ventricular origin are represented in the electrocardiogram by ventricular complexes in which the chief initial deflection is upward in lead I. Ventricular premature contractions of left ventricular origin are represented in the electrocardiogram by ventricular complexes in which the chief initial deflection is downward in lead I. (*b*) The clinical electrocardiograms at present ascribed to block in the right branch of the bundle of His indicate block in the left branch, and vice versa. (*c*) In so-called left ventricular preponderance the electrocardiogram is dominated by right ventricular effects and vice versa.

Epinephrine Test in Hypertension.—Under approximately standard conditions, series of subcutaneous injections of 1 cc. of epinephrine were given by Jensen to a number of normal persons, patients with hypertension, and others in whom the reaction was thought to throw light on the phenomena observed in hypertension. Persons with normal cardiovascular systems responded with a slow rise and a subsequent slower decrease of pressure. While the height of the excursion was but slightly accentuated after subsequent injections, the time consumed in reaching the maximum height of the pressure was markedly shortened. The cases of hypertension fell into two groups which were clinically indistinguishable. In the first group no definite change could be ascribed to the first injection of epinephrine, while the other cases of marked hypertension responded with a brisk and intense increase of systolic blood pressure. When the test was repeated, all the patients with hypertension responded with intense rises of pressure. In cases of early or intermittent hypertension the conditions found were like those of the former group of advanced hypertension, but less pronounced. Statistically it was found that the ratio of the difference and of the probable error of difference between the standard deviations from the average readings following the first and the repeated injections of epinephrine was significant in the first group, in those hypertensive patients in whom the response was absent on the first injection. The diastolic pressure decreased after all the injections, but the time required to return to normal was longer in the patient with hypertension than in the normal person. It was not influenced by repetition of the test. The increase in heart rate and the occurrence of cardiac irregularities were not influenced by the state of hypertension or by repetition of the test. The blood pressure reaction of epinephrine in hypertension did not depend on the level of the blood pressure, the size of the heart, presence or absence of kidney disease, or the level of the blood calcium. No satisfactory explanation could be offered for the absence of response in some individuals with hypertension or for the change in response between first and subsequent tests. The clinical epinephrine reaction is not due to peripheral vasoconstriction. In fact, a vasodilatation is present which indicates that the systolic rise is of cardiac origin. The intense increase in the patient with hypertension is thought to be related to the general instability of the hypertensive blood pressure. This instability is briefly discussed and considered mathematically.

Polypoid Fibroma of Left Auricle Causing Ball-Valve Action.—A case of intracardiac tumor arising from the interauricular septum is reported by Houck and Bennett. They have not found any record of this condition ever having been diagnosed before necropsy. A tumor of this type may produce a ball-valve action in every way similar to the action of a ball thrombus.

Aneurysms of Bronchial Arteries.—A case of multiple, saccular aneurysms of the bronchial arteries is reported by Jacobi, the first recorded in the literature. Death resulted from asphyxia caused by tracheal occlusion by the aneurysm. The etiology is shown definitely to be syphilitic, a rather unusual finding in aneurysms of smaller arteries. Many other small and several medium sized arteries showed syphilitic involvement varying from the early lesions of endarteritis of the vasa vasorum and lymphocytic perivascular infiltration of the adventitia to extensive destruction of the elastic lamellae. The rôle of the supporting external structures in the formation of the aneurysms of the intercostal arteries and aorta in this case is indicated.

Nephrosclerosis (Chronic Interstitial Nephritis) in Childhood. A. G. Mitchell, Cincinnati.—p. 345.
Benjamin Rush, 1745-1813. J. Ruhräh, Baltimore.—p. 389.

Encephalography in Cases Presenting Fixed Lesions of Brain.—Crothers et al. believe that encephalography should be used before final judgment is passed on the future of children severely handicapped by fixed cerebral lesions, unless other less severe methods are demonstrably adequate. Encephalograms, properly taken and intelligently interpreted, give definite information of positive value in at least half of properly selected cases. In the remainder, negative facts of importance can be established.

Buffer Capacities of Various Milks and Proprietary Infant Foods.—An attempt has been made by Holm and Webb to evaluate quantitatively the buffer intensities of various milks and infant foods over the range of hydrogen ion concentration concerned in digestion. They conclude from their results that in the majority of cases of infant feeding the nature of the curds formed is of greater importance than is the buffer capacity.

Nutrition of Children on Mixed and on Vegetable Diet.—From the results of feeding tests made by Lane and Bosshardt there appears no reason to conclude that a scientifically balanced milk diet, including 1½ pints to 1 quart of milk a day per child, produces greater growth or better health in growing children from 7 to 15 years old than a scientifically chosen vegetable diet furnishing a smaller amount of calcium. If there is a greater calcium storage on the milk diet than on the vegetable diet, a supposition which does not appear justified by the gains in height and weight or the other data here presented, there still would seem to be no reason for assuming such excessive storage advantageous for the general health of growing children. Excessive calcium storage may possibly obscure a clear perception of the function of other factors in the diet, whether it is that of the calory-producing nutrients, the various minerals and vitamins or the acid-base equilibrium of the blood. A diet of vegetable foods carefully selected with special reference to the quality and quantity of the protein, low in fat, comparatively high in carbohydrate, with adequate amounts of the various minerals and high in vitamins produced in ten weeks as satisfactory increase in all physical measurements observed in children from 7 to 15 years old, and in most cases greater increases, than a similarly carefully planned milk and meat-containing diet.

Acute Obstructive Laryngitis.—From the bacteriologic study made by Bradford and Leahy of sixty-six cases, it is suggested that green-producing cocci may be of etiologic significance in certain types of acute obstructive laryngitis simulating laryngeal diphtheria.

Nutrition of Sick Children.—Peterman and Hug state that the food requirements of children with chronic bone disease, especially tuberculous disease, are not high but should exceed 50 per cent above the basal requirements calculated on the basis of the "normal" or expected average weight and the height. For patients from 2 to 6 years of age, more than 90 calories per kilogram of body weight should be given; for those from 6 to 12 years, more than 80 calories per kilogram are necessary. These requirements are approximately those for normal, well, active children, but they must be supplied to the sick children in bed. The effects of concentrated foods and further modifications of the diet are being studied. Dental caries did not develop in any child.

Normal Closing Time of Foramen Ovale and Ductus Arteriosus.—An attempt was made by Christie to standardize the knowledge of the normal anatomic closure of the foramen ovale and of the ductus arteriosus by an anatomic and statistical method. This closing time of the foramen ovale was found to occur prior to twelve weeks after birth in 87 per cent of 590 normal hearts of infants from 1 day to 1 year of age. Closure of the ductus arteriosus occurred prior to eight weeks after birth in 88 per cent of 558 normal hearts of infants from 1 day to 1 year of age.

Chondrodysplasia.—The case reported by Blount belongs to one of the rarer forms in which multiple enchondromas are present with no exostoses in the patient or the family.

Value of Acid Neutralization in Treatment of Gastric and Duodenal Ulcers.—Palmer presents data bearing on the rôle of free gastric acidity in the rate of healing of gastric and duodenal ulcer. In the experiments made by him, two groups of patients were subjected to substantially identical types of treatment except for the fact that in one, the so-called alkali group, an effort was made to neutralize the free acidity throughout the entire digestive period, whereas in the other, the so-called beef-tea group, gastric secretion was purposely stimulated in order to maintain as high a free acidity as possible. Conclusions were drawn regarding the results in each group by observing the rate of desensitization of the pain-producing mechanism. The most significant result in these experiments is that two thirds of the patients in group 2 became free from spontaneous distress during the period of administration of beef tea and acid-insensitive without alkali therapy, indicating thereby desensitization of the pain-producing mechanism. This indicates that some progress has been made by the reparative processes in the ulcer. Stimulation of gastric secretion by means of the hourly feeding of beef tea did not stop them; it did not stop the natural tendency of the ulcer to heal spontaneously. This constitutes further evidence that, regardless of what the etiology of ulcer may be, and regardless of the cause of chronicity, the natural and usually the dominating tendency in any given ulcer is toward healing. The next most significant observation is that neutralization of the gastric free acidity by means of alkalis definitely increased the rate of desensitization of the pain-producing mechanism. There is reason to think that some correlation exists between this and the healing process, that desensitization signifies some progress toward healing. The conclusion seems reasonable, therefore, that neutralization of the gastric free acidity favors healing. This may be due to protection of the ulcer surface from the destructive action of hydrochloric acid, to decreased gastric emptying time, to diminished spasm, or perhaps to other unknown factors. But, regardless of what the explanation may be, healing apparently proceeded at a faster rate in the alkali group.

Laboratory Studies in Epilepsy.—An intensive laboratory study of seventy-three epileptic patients was made by Felsen and the observations were compared with the more limited investigations of other authors. The data reveal significant variations and suggest a more careful study of individual epileptic patients as a clue to the pathogenesis of epilepsy.

Chronic Intractable Type of Bronchial Asthma.—Kahn concludes that there exists a type of asthmatic person in whom, even in the absence of other complications, antibody formation against allergic antigens or the allergen resistance factor, whatever that may be, is apparently greatly reduced or nonexistent, precisely as is the case analogously in tuberculosis and other bacterial infections. In the absence of antigen reproduction, such as occurs in bacterial infections, there is probably combined with this lowered faculty of antibody formation a definite inability to excrete promptly the toxins elaborated by such allergic antigens following their complete withdrawal. Eosinophilia is usually absent in these cases. The usual diagnostic skin tests cause negative reactions, and if pollens are used, are dangerous. In these cases there is gradual, and at times rapid, development of polyantigenic sensitiveness of high degree. A small but appreciable percentage of these patients recover a certain amount of antibody formation and relief and even freedom from symptoms after many weeks or months of persistent elimination of antigenic contact without the institution of other therapeutic measures. While there is no laboratory proof to support these contentions, the clinical results secured offer rather conclusive proof. There exists no known reason why a patient should not fail to develop antibodies to allergic as well as to bacterial antigens.

Evaluation of Prognosis in Arterial Hypertension.—Stieglitz feels that the prognosis in individual instances of arterial hypertension should be based on several variable factors and does not necessarily coincide with the statistical average prognosis for groups of hypertensive persons. The factor of age is not of great moment. The factor of the etiologic background accounting for the hypertension is significant. Likewise are the status of the cardiac and of the renal reserve of importance. Most significant of all is the stage at which the vascular disease is encountered; whether the hypertension is of purely spastic origin or whether slight, moderate or extensive fibrotic changes have already taken place in the vessel walls. Spasticity and hypertonicity, no matter how severe, are amenable to therapy. Fibrotic scarring and replacement of degenerated muscle cells are not amenable to therapy but represent permanent injury. The degree of relaxability can be determined easily and rapidly by noting the response of the arterial tension to the inhalation of amyl nitrite. The type of response encountered has proved of great assistance in properly evaluating the individual prognosis. In fifty instances, only one incorrect preliminary prognostic opinion was given. Relaxability of the arterioles is evidence of vascular disease relatively early in its pathogenic development, whereas the rigid fibrosed arteries of arteriolar sclerosis respond little or not at all. This procedure makes it easier to answer the patient's justified request for specific information relative to his outlook.

Postoperative Results in Toxic Goiter.—Clarke and Black have studied 181 cases of thyroidectomy according to the age of the patient, distribution and duration and incidence of symptoms. It was determined that 70 per cent of the patients lost weight while 30 per cent showed no change or even gained weight. The most common pathologic process in the thyroid was colloid adenoma, hyperplasia being much less frequent. The mortality rate was 6 per cent. The pulse rate at admission, minimum before and maximum after operation with the rate at discharge were ascertained. These showed a definite division into groups according to the mean and extreme rates, the ratios conforming closely to those observed for the weight changes. Seventy-six cases were studied after an average elapsed time from operation of two and one-half years. Only 58 per cent of the patients had gained weight; the pulse rate was below normal in a group approximating the same number who had not gained weight since operation. The blood pressure showed an unusually high number who had developed abnormally high blood pressures since operation. They found 16 per cent well, 40 per cent moderately improved, 34 per cent slightly improved and 10 per cent showing definite recurrences. Hence they consider surgical intervention unsatisfactory in a large group of these patients but consider that its benefits could be improved by more accurate preoperative selection, the weight being an accurate preoperative guide. Surgical intervention is only substitutional therapy, substituting the dominant myxedema for the less dominant state of hyperthyroidism and not in any way altering the real constitutional condition but only alleviating it. A perfect surgical result depends on the chance development of equilibrium between the hyperthyroidism and the developed myxedema. The disease hyperthyroidism is primarily a problem of the internist, and its ultimate real cure will come through real control of the constitutional condition and not by surgically interrupting one link or substituting another less disturbing symptomatic or neutralizing disease.

Postmortem Blood Chemistry in Renal Disease.—From a postmortem study of the creatinine and urea content of the blood specimens in 100 cases, Polayes et al. conclude that blood creatinine determinations are often helpful as an aid in determining the status of the renal function during life. The urea values are not as helpful as the creatinine figures. A creatinine content of 4 mg. or more per hundred cubic centimeters of blood obtained post mortem indicates marked creatinine retention during life and therefore severe renal insufficiency.

Fatal Human Anaphylactic Shock.—A case of fatal anaphylactic shock after a single injection of diphtheria antitoxin is reported by Bullowa and Jacobi. The pathologic anatomy consisted chiefly of acute pulmonary emphysema, dilatation of the right side of the heart, general venous stasis and visceral congestion; the left side of the heart is contracted and empty. Microscopically, the changes consisted chiefly of thickening of the arteriolar wall, especially in the lungs. These anatomic changes are presented as corroborative morphologic evidence to substantiate the experimental work on the pathogenesis of fatal anaphylactic shock reviewed. This consisted chiefly in overfilling of the lungs, which remained distended, a drop in the peripheral blood pressure with a concomitant rise in the pulmonary arterial pressure, a progressive weakening of cardiac contraction and a slowing and final stopping of the heart, with the right auricle and ventricle in diastole and very much dilated. The cases of anaphylactic shock that came to necropsy are reviewed in detail. Doubt is cast on the rôle of the thymus in such cases.

Influence of Special Breakfast on Basal Metabolism of Patients.—Two series of experiments were conducted by Wang and Hawks on three normal persons and on twenty-three subjects with a pathologic condition, including twelve patients with thyrotoxicosis. The basal metabolism varied from + 74.6 to — 14.6 per cent from the Harris-Benedict standard. In the control series two tests were made one hour apart, while in the second a special breakfast recommended by Benedict was given after the first test, followed by another test an hour later. The average difference of the two tests in the control series was 0.08 per cent, while that of the second series was 0.53. On the basis of their experimental data, they conclude that the special breakfast may be used with advantage to patients who are extremely nervous and who have late appointments for their basal metabolic test.

Affectepilepsy and Hystero-Epilepsy.—The thirteen cases cited by Notkin include three so-called hystero-epilepsies, two alcohol epilepsies, three poriomanic affectepilepsies and five other cases of psychopaths with so-called affectepilepsy. On the basis of this material, an attempt is made to show the possibility of an hysterical manifestation transforming itself into a more severe organic reaction of an epileptic nature. Considerable doubt is expressed as to the ultimate deterioration in all cases of the idiopathic variety of epilepsy. Bratz's theory of the nonoccurrence of petit mal attacks in affectepilepsy is dispelled by a critical consideration of his material and citation of his own cases. The mechanism of the attacks in affectepilepsy is explained by the process of spontaneous hyperpnea frequently seen in psychopaths during affective states. Attempt is also made to explain the phenomenon of functional aphonia by the same mechanism. Vasomotor disturbances during emotional states are also offered as a mechanism for the attacks, and the possibility of overflow of senso-affective stimuli from the thalamus is suggested. Alcohol is the expression of psychopathy or may be an incidental manifestation in patients with affectepilepsy. Alcohol itself may produce convulsions as a toxic agent or by causing biochemical alterations. The suggestion to omit all the various classifications is made and to consider one cryptogenic group of convulsive states with a multiplicity and variety of etiologic factors in addition to the "something" which gives rise to the convulsive attacks.

Tuberculosis and Uncinariasis.—Sixty-eight cases are presented by Colby and Schaffle, in forty-three of which both hookworm disease and tuberculosis were present, while there were twenty-five cases of uncinariasis which had been referred with a diagnosis of tuberculosis.

Regional Anesthesia in Treatment of Fractures and Dislocations.—Nerve block anesthesia is preferred by Highsmith over general narcosis and local infiltration anesthesia in the treatment of fractures and dislocations. Thirty-five cases are reported.

Synovial Fluid in Infections and Neuropathic Arthritis.—A report of the bacteriology and cytology of the synovial fluid in 125 cases of arthritis is given by Shands. There were 105 patients with chronic infectious arthritis. Streptococci were recovered from the synovial fluid in 26.7 per cent of this number. The total percentage of positive joint cultures was 38.1. Of the twenty-eight positive cultures of streptococci, twenty-three were of the viridans type. The average white cell count and the average percentage of polymorphonuclears was distinctly higher in the group in which positive cultures were obtained. Studies were made on the synovial fluid of four acute gonorrheal joints, four joints with acute synovitis, and two infectious joints of miscellaneous grouping. There were ten patients with neuropathic arthropathies, nine of whom had definite Charcot joints. Bacteria were recovered from the synovial fluid of four of this number. Two of the three positive Charcot joint cultures were *Streptococcus viridans.* The cytologic studies in this group were very similar to those of the chronic infectious arthritic joints with negative cultures.

Empyema in Children Treated by Tidal Irrigation and Suction.—Thirty-six children (fifteen years or less of age) have been treated by Hart by tidal irrigation, with five deaths. All of the fatal cases were in a serious condition at the time of operation, while four of the five were apparently hopeless. Each of the four patients who died in the hospital had a bilateral empyema. The larger number of patients were in the younger age groups (72 per cent 5 years of age or less) where the mortality is usually high. Fifteen of these patients were 2 years of age or younger, with one death in the hospital, giving a hospital mortality of 7 per cent. No patient in this age group came to necropsy with an empyema that had not been diagnosed and drained. In the same age group during the preceding twelve years there was a 40 per cent mortality among operative cases; 25 per cent came to necropsy undiagnosed and 10 per cent of the patients died without operation, after a diagnosis had been made by thoracentesis. The organisms were diverse, the pneumococcus type I and the influenza bacillus apparently causing the most serious infections. The complications not referable to the method of treatment have been numerous, diverse, and often multiple. The complications referable to the method of treatment have been almost negligible. One patient developed a superficial abscess, secondary to an osteomyelitis of the rib, seven months after discharge from the hospital. No other patient has shown any trouble or symptoms referable to the empyema. No patient has been discharged from the hospital with a draining sinus. The duration of the drainage has been greatly reduced. No patient has developed a chronic empyema.

Cause and Cure of Bath Pruritus.—Gaines explains the neurogenic mechanism of this condition and relates his treatment, which consists of measures aimed at restoring the activity of the sweat glands—having the patient submerge in very hot water; remain until perspiration is well established; emerge and dry quickly in a warm room free of draft; avoid friction with towel and don his clothes while his skin is still moist. As the patient continues to escape his dreaded paroxysms, not only is the emotional factor eliminated but the irritability of his skin from repeated rubbing is allayed.

Etiologic Types of Heart Disease in Professional Men.—A selected group of 163 professional individuals was studied by Horine and Weiss. There were 99 physicians, 26 clergymen, 20 attorneys and 18 dentists. They found that the etiologic types of heart disease as encountered in the learned professions do not differ from the types found in the lay population. Clinical evidence is presented to show that a diagnosis of hypertensive heart disease may be made even in the presence of a normal or subnormal blood pressure. The presence of peripheral arteriosclerosis of itself does not justify the diagnosis of arteriosclerotic heart disease. The coronary basis of angina pectoris is stressed. Patients with certain functional heart disturbances resulting from a lowered basal metabolic state should be placed in the hypothyroid heart group. The average physician with heart disease is a cooperative patient.

Malnutrition.—Eby noted marked improvement in undernourished and underweight children following a three months period during which each child in the nutritional clinic in the various schools was given two glasses of milk and two bananas in addition to his regular lunch during the school day.

Treatment of Stricture of Urethra with Bipolar Current.—Livermore uses the bipolar current in all urethral strictures which do not promptly respond to dilation. The electrode is applied to the stricture through the urethroscope, the bipolar current turned on and the strictured band or bands thoroughly fulgurated. It has been his practice to fulgurate at one point, endeavoring to apply the electrode entirely across the strictured tissue. In a week or ten days, sounds are passed.

Simplified Method of Blood Chemistry Analysis.—The procedure employed by Matthieu is as follows: One part of oxalated blood is added to nine parts of the reagent. It can be filtered immediately. The filtrate can be used exactly in the same way as the one obtained by Folin's method. The reagent has the following composition: Ten Gm. of sodium tungstate is dissolved in 1,000 cc. of fifteenth normal sulphuric acid. The solution is stable for at least three months. Sometimes a slight precipitate occurs after a few days, but this does not interfere with the method. In this case the reagent should be shaken before being used. It is recommended to cover the surface with some toluene.

Psychic Treatment of Dementia Praecox by Lectures.—Lazell is convinced that major neuropsychiatric conditions, such as hyperthyroidism, epileptiform convulsions, dementia praecox of the hebephrenic form, anxiety neuroses and the manic-depressive groups not only are curable by the lecture method but also are curable when the lectures are given to groups of patients. The best results have been obtained in those patients who have been hospitalized over a considerable period of time, who are under control and who have attended at least two series of lectures. The treatment should extend over at least six months, with a close following up during the first few months after return to civil life. The group method is the only practical and successful method of approach in the treatment of neuropsychiatric cases in which large numbers of patients are involved. The group-lecture method is of the highest importance in solving the greater problems of the public mental health. It should be extended to reform and industrial schools, to state hospitals for the mentally disordered, and to penitentiaries. Psychopathic clinics should be opened in all large centers of population to assist the great numbers of borderline cases before they have broken completely and become psychotic.

Tuberculous Cavitation.—In a series of forty-three patients dying of pulmonary tuberculosis and coming to necropsy, Blumberg says 92 per cent showed cavities. Cavitation was bilateral in 63.2 per cent, and unilateral in 36.8 per cent. Involvement of both upper lobes and the left lower lobe existed in 68 per cent. Intestinal tuberculosis was a complication in 81.87 per cent, laryngeal tuberculosis was found in 15.8 per cent, and spontaneous pneumothorax was present in 6.4 per cent. Healed and healing lesions were found in patients who died with advanced pulmonary tuberculosis. Roentgenologic evidence over three and one-half years demonstrated that pulmonary cavities may disappear and show no recurrence. This is the case when the prevailing type of reaction to the disease is overwhelmingly fibrous. From this it can be assumed that these cavities had healed, in view of the fact that healing was evidenced in cases at necropsies. Deposits resembling epithelium were found to line some cavities. Some cavities remain stationary without manifestating clinical activity.

Malarial Treatment of Dementia Paralytica.—Holmes has given eighty-one inoculations to fifty-eight patients. Two patients also contracted malaria. Intravenous inoculation was practiced when possible, the intramuscular route being second choice. The amount of blood used varied from 1 cc. to as much as 25 cc. in one case, the usual amount being from 5 to 6 cc. It was not found necessary to take the blood from the donor during a paroxysm; blood taken at any time was effective. The patients were not selected, except that only those who were in fair to good physical condition were treated. Tertian malaria was used as far as possible; however, this report includes a number of patients who had estivo-autumnal malaria. All of these patients had had some and most of them a great deal of antisyphilitic treatment before their inoculation with malaria. From a clinical standpoint 21 patients showed no improvement or continued to deteriorate; 1 patient died; 21 showed slight improvement, 12 showed moderate improvement, and 3 showed marked improvement. Serologically, blood Wassermann tests were not affected. The spinal fluid globulin showed no change. The spinal cell count was unaltered in 36 cases, there was a slight reduction in 5, a moderate reduction in 3, marked reduction in 2, a slight increase in 1, and a moderate increase in 1 patient. The spinal fluid Wassermann test showed no change in 26 cases, slight modification in 17, moderate improvement in 3, and marked improvement in 1; it was slightly more positive in 1 patient. The colloidal gold curve showed no change in 18 cases, slight improvement in 19, moderate improvement in 7, and in 2 patients showed a slight change for the worse. It was the experience that the most favorable results could be expected in the manic types and in those patients who were given early treatment. Not much can be expected in old markedly deteriorated cases. Any improvement made was noted within a period of two or three months, and usually within a few weeks.

Asthmatic Child.—By way of prophylaxis, Bray urges that intermarriage between allergies should be discouraged. Children of allergic parents should be watched from birth. Bronchitic attacks in eczema or prurigo children should be regarded as potential asthma; coughs should be quickly investigated as well as sneezing, wet noses, or coryza on the slightest provocation. Furniture and bedding for these children should be of the simplest kind. As inhalant sensitization is acquired, kapok should substitute feathers or hair as bedding; furs and pets should be restricted. At the onset of any symptoms that may be of an allergic nature, thorough examination and testing both of the skin reactions and of the gastric contents should be advised. Septic foci, as teeth, adenoids and tonsils, should be remedied, and early breathing exercises and proper convalescence arranged after the infective diseases of childhood.

Pulmonary Lesions in Rheumatism.—In twenty-five cases of the rheumatic infection reviewed by Findlay there was a pulmonary complication and definite evidence of a rheumatic carditis. In sixteen of the cases the cardiac lesion was pericarditis with effusion. In nine of these sixteen cases the condition was one of effusion into the pleural sac. In eight of the cases there was endocarditis. In three of these cases of rheumatic endocarditis there was a left-sided pleural effusion. In the whole series of cases the pleural effusion has in the majority of cases been situated on the left side. The pleural effusion occurs most frequently at the left base and should always be suspected when the percussion note is impaired at the left base, even if the respiratory murmur is intensely tubular in character and râles are present. Pulmonary lesions in rheumatism are of the nature of (*a*) an intercurrent disease (lobar pneumonia) or (*b*) a terminal hypostatic or bronchopneumonia complicating cardiac disease.

Infection Due to Salmonella Type Dublin.—The three cases cited by Souper et al. make a total of five cases encountered in Aberdeen since 1925. The first recognized case occurred in a man, aged 38, the second in a girl, aged 2 years, and of the three cases now recorded, two occurred in infants, and one in a boy aged 5 years. All must have had a septicemia, since in three cases the organism was isolated from the blood, in one case in which the blood cultures were inadequate the organism was isolated from the urine, and in the fifth case from the cerebrospinal fluid, which, presumably, became infected secondarily from the blood. Two out of the five patients died. In four of the cases the home conditions were investigated, but no other case of illness had occurred in any other member of the various families. Further, the fifth case actually occurred in a hospital ward in which there were eighteen other infants. Here a complete investigation was made of the feces and urine of five members of the nursing staff and of all other patients in the ward, but the results were entirely negative. If milk had been the vehicle of infection in the fifth case, then only one case occurred out of a total hospital population of some 350 children and adults.

Hemoglobinuria in New-Born.—Infective hemoglobinuria of the new-born is suggested by Smith as a suitable designation for this disease. Experimental work on the excretion of hemoglobin in rabbits and the deposition of hemosiderin in the cells of the convoluted tubules is confirmed. The pathology of renal obstruction in this and other forms of hemoglobinuria is surveyed and suggestions for treatment made.

Results of Decapsulation in Nephritis.—An analysis is made by Campbell of twenty-three cases of subacute nephritis in children in whom decapsulation of the kidneys had been performed because of failure to respond to medical measures. Of these twenty-three patients, twelve have either completely or in great part recovered. Examination of the records failed to reveal any common factor that might be of assistance in the recognition of a case suitable for operation. From data recorded it cannot be concluded that the ultimate result in a case of subacute nephritis is influenced by the operation of decapsulation. Certain cases do show definite improvement after operation, this improvement being reflected principally in disappearance of edema. There is no evidence that improvement in kidney function follows as a result of the operation.

Epithelioma of Lip Developing on Site of Recurrent Herpes Simplex. N. Burgess.—p. 249.

Massive Collapse of Lung (Active Lobar Collapse).—Eight cases are cited by Morison. He is certain that, in the examination of the chest, the more one keeps in mind the possibility of active lobar collapse the oftener it will be found, more especially in children and young adults. Active lobar collapse must be clearly differentiated from massive collapse of the lung of a passive character. The function of the musculature of the bronchial tubes may be deranged by various causes acting on the sympathetic and vagal innervation either directly or reflexly. The weight of evidence is in favor of the theory that spasm of the bronchial musculature is the essential feature of active lobar collapse, but the disturbance of the sympathetic innervation must also be taken into account.

Lipoid Nephrosis.—Moore et al. are of the opinion that lipoid nephrosis is in reality a chronic mild glomerulitis. Two bacterial toxins are definitely known to select the glomerulus of the kidney for attack. They are the toxins of the diphtheria bacillus and of the hemolytic streptococcus. The cause of lipoid nephrosis is unknown, but there is justification for suspecting a bacterial origin. One organism, the pneumococcus, suggests itself for study. Many of these patients die of pneumococcal peritonitis.

Insoluble Precipitates in Diphtheria and Tetanus Immunization.—Glenny's experiments show that the immunity produced by the precipitate formed by the addition of alum to tetanus and diphtheria toxoids is greater than that produced by toxoid alone. The increase in certain experimental conditions has reached even a thousand fold.

Tetany After Exercise.—A case of tetany after exercise has been investigated by Lawrence and McCance and found to be due not to the exercise per se but to an alkalemia caused by prolonged (presumably functional) overbreathing after the exercise was completed.

Famine Edema.—The case recorded by Aykroyd was observed at St. Anthony Hospital, North Newfoundland. For a variety of reasons, the poorest Newfoundland families in late spring and early summer may be reduced to a diet made up almost entirely of white flour bread, with scanty additions in the form of molasses, salt meat and salt fish, and little else. At times the additions may run out and the family be reduced to bread and molasses. Such a regimen usually produces beriberi, a common disease in Newfoundland. Newfoundland beriberi is identical with the tropical rice eater's disease, and both wet and dry forms may be observed, the latter being by far the commoner. This patient developed an obscure dropsical condition which followed a long period on an extremely faulty diet. It is peculiar that a patient who had practically lived on dry bread for six months or longer should develop this condition rather than one of the better known deficiency diseases.

Health of Worker of Today.—Oliver contends that the health of the workers of today is better than it was half a century ago; the conditions under which labor is carried on have improved, the hours of work have been shortened so that the working man has more rest and leisure than previously, and but for the industrial depression matters would have been still better than they are. The one circumstance that stands out prominently and calls for special comment is the lengthened duration of sickness and the greater length of time taken to recover from wounds and fractures than formerly, notwithstanding improved methods of medical and surgical treatment and despite the fact that there has been no corresponding increase in the number of claimants. As the types of illness from which the working classes suffer have not changed and there has been no recognizable impairment of their vital resistance and power of recovery, it is clear that, apart from the aged members, it is not the duration of the illness per se which is the demeaning agent but the period given to convalescence being unduly protracted.

Sun Treatment in England. — Gauvain believes that the August holiday which is enjoyed by the bulk of the population, and which is so often spent at the seaside under conditions different to those of the remainder of the year, is of great help to restore minds and bodies jaded and in need of stimulation and change. Additional exposure to sunlight means an additional tonic and, like all tonics, must be wisely employed and not abused. Not only does it have a beneficial effect on the general physique and on the general power of resistance to disease, but it has an equally beneficial effect on the mind. The sun bather who is benefiting from insolation is always cheerful and happy. None are brighter in their spirits than those who are sun worshippers in the most literal sense, and not only are they more vigorous, more alert, gayer in spirits, but there is a stimulating effect on the mentality of patients receiving insolation. The effect of sun treatment on the nude recumbent patients at Alton and Hayling island was to raise their mental activity on an average of 10 per cent above that of the ordinary child in the physically defective schools who was not able to enjoy insolation. If all the school children had the benefit of at least one or two months insolation annually there is no doubt that it would have a profound beneficial effect on their education generally and the improvement of both their bodies and their minds. Sun treatment, then, is of the nature of a shock treatment, comparable in some ways to protein shock.

Bicolored Guaiac Test for Cerebrospinal Fluid.—The cerebrospinal fluids of 140 patients with diseases of the nervous system have been examined by Greenfield and Stern by the bicolored guaiac reaction. A Lange colloidal gold test has also been done on each of the fluids for comparison with the new reaction. Their results justify the statement that the bicolored guaiac test is of the same practical value as the Lange test in the laboratory diagnosis of neurosyphilis. The bicolored guaiac test runs parallel with the Lange reaction in that certain cases of disseminated sclerosis give positive results. It differs from the Lange reaction in that negative reactions may be obtained in spite of great protein increase. The ease and certainty with which a good bicolored guaiac suspension can be prepared from stock solutions gives the test a definite advantage over the Lange reaction, since good colloidal gold solutions may be difficult to prepare and there is no satisfactory method of testing them except by their reaction to known specimens of cerebrospinal fluid. The Lange reaction is therefore suited only to laboratories in which a large number of specimens of cerebrospinal fluid are examined. The disadvantages of the test are that a comparatively large quantity, 1 cc., of cerebrospinal fluid is required for the test, and that it is not possible to judge what the final reaction will be under twelve hours, whereas with the Lange reaction a fair estimate may be made after half an hour. For these reasons the authors suggest that this test should replace the Lange test in the routine examination of the cerebrospinal fluid. But when difficulty arises in the preparation of a good colloidal gold reagent, the bicolored guaiac test may be substituted or, owing to its more standard nature, may be used as a control for the Lange test.

Etiology of Cholecystitis.—Material from 106 cases of cholecystitis was examined bacteriologically by Williams and McLachlan. Streptococci have been found in the cystic gland or gallbladder wall in 16 per cent of these and *B. coli* in 20 per cent. Streptococci have been found in the contents in 20 per cent and *B. coli* in 19 per cent. The streptococci isolated have been largely of the type that occur normally in the bowel. No evidence has been obtained that *B. coli* is merely a secondary invader and that the streptococci are the primary invaders. The rôle of both, whether they are primary or secondary invaders, seems to be similar. The organisms isolated have little power of localizing electively in the gallbladder of experimental animals.

Pyrogenic Action of Sulphur in Olive Oil.—Nine cases of dementia paralytica and nine cases of nonsyphilitic functional mental disorder have been treated by Shilvock. No patient has been made worse, either mentally or physically. Abscesses have not appeared at the site of injection. Good pyrexial reactions follow, but their extent may be dependent on the patient, apparently on the activity of the thermogenic center. Thus, one patient regularly had pyrexias of 105 F. with malaria and gave the same response to colsul. Another, however, regularly gave poor pyrexias with malaria but much better with colsul. The pyrexias follow the injection, and there is no delay due to an incubation period. No additional disease is induced nor are agents required to control it. Therefore a febrile state can be induced at any time of the year and the pyrexias can be timed as desired and produced by intramuscular injection. The agent seems to cause a focal reaction in the areas of chronic sepsis. The latter reaction indicates its value and probable mode of action in the treatment of mental disorder.

Expulsion of Ectopic Fetus Papyraceus After Uterine Curettage.—The pregnancy in McFadyean's case was isthmial. The fetus died when 82 days old and was retained until the date of operation, seven weeks later.

Unusual Route of Infection in Cholecystitis.—Rutherford's case was typical. An operation was performed. In apposition with the gallbladder were the cecum and an inflamed appendix. Cholecystectomy and appendicectomy were performed, and the patient made an excellent recovery.

Preventive Tuberculosis Vaccination with B C G Vaccine in Kief.—In an effort to determine the effects of B C G vaccine, Nechtadimenko et al. conducted a series of experiments on guinea-pigs and rabbits, which they inoculated with from 0.1 to 100 mg. and even 1 Gm. of the vaccine. The injections were given subcutaneously, intravenously and intracardially. From their laboratory tests they conclude that (1) B C G vaccine determines the specific tuberculous process in the organs, but (2) this process normally evolves toward cure except after excessive doses and (3) the lesions thus produced are not reinoculable, or at least in animals in which they are reinoculated, extensive lesions are not produced. Also, 155 new-born infants were vaccinated, 87 of whom lived in a tuberculous environment or in bad sanitary conditions. Most of the children lived more than two and one-half years. Of five deaths, four were due to causes other than tuberculosis. The authors' observations confirmed the harmlessness of the B C G vaccine and established the necessity of isolating the child from all source of contagion during the first month after vaccination. Cases of infection after B C G vaccination were in general mild and the general mortality and the tuberculosis mortality were reduced by the vaccination.

Harmlessness of B C G Vaccine in Infants.—By means of their experiments, Chaussinand and Tempé demonstrated the harmlessness of B C G vaccine given to infants by intraperitoneal, peroral and subcutaneous injections in total amounts varying from 2 to 60 mg.

Intramuscular Injection of B C G Vaccine in Children.—Chaussinand expresses the opinion that the sole advantage of the intramuscular route for injecting B C G vaccine over other methods is the rapid appearance of allergy. Doses of 0.05 or even sometimes of 0.02 mg. generally produce a positive cutireaction at the end of three or four weeks, whereas this reaction appears only toward the sixth week after a subcutaneous injection. Two simultaneous intramuscular injections of 0.025 mg. each would have a beneficial effect on new-born children who cannot be isolated from their infectious surroundings and in whom it is desirable to produce a rapid immunization.

Vaccination of Rabbits and Guinea-Pigs Against Cerebral Tetanus.—Subcutaneous or intraperitoneal vaccination of animals by means of a tetanus anatoxin brings about the formation of tetanus antitoxin in the general circulation. The cerebrospinal fluid of animals thus treated never contains antitoxin. Mutermilch and Salamon also found that the intrameningeal vaccination of animals engenders the formation of antitoxin in the general circulation as well as in the cerebrospinal fluid. Guinea-pigs actively or passively vaccinated either subcutaneously or intraperitoneally usually resist the inoculation of tetanus toxin in the brain. Rabbits, however, are usually sensitive to this inoculation. Animals vaccinated intrameningeally are regularly refractory to the inoculation of tetanus toxin in the brain. The presence of tetanus antitoxin in the cerebrospinal fluid is the sine qua non of the antitetanic neuraxial resistance of vaccinated animals. In those vaccinated intrameningeally the antitoxin is present in the body fluids, while in those vaccinated subcutaneously or intraperitoneally the antitoxin passively penetrates from blood to fluid.

Sero-Attenuation and Immunity in Measles.—The sero-attenuation method of prophylaxis seems to confer a relatively lasting immunity while the absolute seroprevention method does not, according to the numerous observations made by Debré et al. They also record cases in which the attenuation of the disease by the serum was too great to confer more than a slight immunity. A minimum of clinical manifestations seemed indispensable in order to obtain immunity that was at all lasting. Both the disease itself and a mild, modified form artificially acquired by sero-attenuation appeared to confer relatively lasting immunity. The length of time that the organism remains immune is unknown.

Essential Primary and Permanent Arterial Hypertension with Severe Hypertensive Paroxysms.—In this case of permanent hypertension during the menopause there occurred first every few months, then every two or three weeks, paroxysms of hypertension in which the tension was too high to be measured by the clinical manometer. In spite of this fact, neither capillary rupture nor left ventricular deficiency resulted; only the ascending aorta underwent a circumferential distention. The azotemic level seemed to be connected with the tension, since it rose with the paroxysms and returned to normal in the intervals. In their treatment of this case, Monier-Vinard and Desmarest found that the permanent hypertension was only temporarily influenced by suprarenalectomy. Spinal anesthesia caused a marked and dangerous hypotensive collapse. Chloroform brought only a moderate lowering of the tension. The authors found that roentgen therapy did not at the time modify the tension although it may possibly have ameliorated it slightly later on. The simple removal of 12 cc. of cerebrospinal fluid through lumbar puncture resulted in a lowering of the tension, which was maintained thereafter although at a figure still above normal.

Mechanism of Syncope: Rôle of Return Circulation.—Cardiac syncope with its consequent drop in blood pressure is ordinarily attributed to a sudden cardiac deficiency and lack of blood in the arterial system. But the absence of blood, in the opinion of Laubry and Tzanck, may be due either to suppression of the cardiac functioning or to arrest of the return of blood from the periphery to the heart. Their experiments showed that the latter eventuality was the more plausible.

Acute Intestinal Occlusion Caused by Inflammation of Meckel's Diverticulum.—In this case a roentgen examination confirmed the diagnosis of acute intestinal occlusion, which operation revealed to be caused by peridiverticulitis. Trémolières et al. emphasize the importance of roentgen examination in the diagnosis. The examination in such cases should be extemporaneous, rapid and without any preparation, and it must be made with the patient in the vertical position.

Insulin in Suspension in Oil. M. Labbé, R. Boulin and Soulié.—p. 1190.

Familial Neurosyphilis.—Sézary does not accept the theory that hereditary nervous syphilis is due to a neurotropic virus distinct from the dermotropic virus of syphilis. He cites the case of a family in which the virus attacked the nervous system of the parents and of one child, sparing the nervous system of the second child but attacking the bones of the nose. The same virus was therefore neurotropic and osteotropic, which proves that it has no definite organotropism.

Testiculo-Epididymal Lesion of Uncertain Diagnosis. Heitz-Boyer.—p. 871.
Regeneration of Neck and Trochanter of Femur After Resection of Head, Neck and Two Trochanters. R. Leriche.—p. 872.

Preoperative Vaccination in Gastric Surgery.—Murard employed preoperative vaccination in eighty-four cases of gastro-enterostomy in an effort to avoid pulmonary complications. Three different vaccines were used. On the whole, the results were somewhat discouraging. In discussing the work, Bazy notes that the absence of specificity in the vaccines usually employed and the difficulty in producing tissue immunity by means of a vaccine injection that does not itself cause a local lesion, seem to indicate that there is no certainty that the organic defenses are sufficiently reinforced by the vaccine to make local complications, pulmonary or other kinds, impossible.

Recurrent Dislocation of Shoulder Treated by Elongation of Coracoid Process.—The dislocation had recurred some sixty times. Wilmoth successfully treated the patient *by creating a subcoracoid, bony abutment.* The extra-articular graft to lengthen the coracoid process and to constitute a stop to oppose displacement of the humeral head was simply put in place without *sectioning the subscapularis muscle or opening* the joint cavity.

Pathogenesis of Hydronephrosis Studied by Retrograde or Ascending Pyelography. M. Chevassu.—p. 923.
Diagnosis of Chronic Pancreatitis. R. Grégoire.—p. 945.

Rupture of Spleen and of Left Kidney.—Goinard discusses the cases of four men in whom severe abdominal injury *was associated with wounds of the spleen and left kidney.* The wound of the spleen in three cases had determined an intraperitoneal hemorrhage. The renal wound had formed a large *perirenal hematoma. The condition of the organs* was such that splenectomy and nephrectomy were necessary. Rapid death ensued in one instance. In the fourth case, the wound in the spleen with internal hemorrhage was treated by splenectomy. There was also hematuria due to a subcortical renal lesion. There was no perirenal hematoma. The patient died after three weeks as the result of postoperative pulmonary complications. The author suggests the following three possible types of incision: a lumbar incision, a transverse abdominal incision, and a median laparotomy incision.

Sacrococcygeal Chordoma: Cases. J. Sénéque and J. P. Grinda.—p. 817.
*Metallic Osteosynthesis: Biologic Considerations. R. Frantz and M. Mayer.—p. 843.

Metallic Osteosynthesis: Biologic Considerations.—In view of the discordance between the perfection of operative means and the uncertainty of prognosis in osteosynthesis, Frantz and Mayer carried out a series of experiments on dogs in order to ascertain precisely the elements to be relied on to establish the relationship between the biologic and the physiologic processes of osteosynthesis. They limited their studies to bone reactions in metallic osteosynthesis for diaphysary fractures and applied to the animals all the metallic devices used on patients in such cases. In a first series of experiments, penetrating and nonpenetrating metallic prostheses were affixed to nonfractured bones. In the second series they were applied to fractured bones. The authors found that a strictly immobile material was well tolerated whatever its volume, whereas a mobile material provoked bone reactions proportionate to the size of the prosthesis. Mobility of the device results in nonconsolidation of the fracture. Removal of the metallic material then often suffices in order to form a bony callus that will assure healing. The more reduced the supporting points of the prosthesis, the more rigorously must immobilization be maintained after osteosynthesis.

29: 537-648 (June) 1930

*Correlation Between Testis and Other Parts of Organism. E. Retterer.—p. 537.
*Diagnostic Errors in Renal Tuberculosis. J. Martin.—p. 556.
Importance of Extrarenal Factors in Phenolsulphonphthalein Elimination. H. Blanc.—p. 571.

Correlation Between Testis and Other Parts of Organism.—Retterer finds that the powerful general action which the testis exercises over all the parts of the organism seems essentially due to the epithelial covering of the seminiferous tubules.

Diagnostic Errors in Renal Tuberculosis.—Martin discusses the difficulties and errors involved in the diagnosis of renal tuberculosis, especially in the cases in which one of the indications may be lacking. He finds that a pyuric kidney, when tubercle bacilli have been found in the total urine, is not necessarily tuberculous; neither is a decided deficiency of urea concentration of one side necessarily an indication of tuberculosis in that kidney. Hence, unless tubercle bacilli are actually found in the urine of a kidney, further explorations and tests should be made even though other signs indicate a diseased organ. Cases occur in which clinical signs point to renal tuberculosis and yet operation reveals no lesions. The author reports one case of this kind, with another in which there were small chronic inflammatory lesions apparently not tuberculous. Yet after operation the symptoms disappeared in both instances.

*Heliotherapy, Climatotherapy and Surgery in Treatment of Tuberculous Ostearthritis. C. M. Bufnoir.—p. 68.
Subtrochanteric Osteotomy: Indications and Technic. A. Trèves.—p. 72.

Heliotherapy, Climatotherapy and Surgery in Treatment of Tuberculous Ostearthritis.—In the opinion of Bufnoir, surgical treatment alone is not sufficient to cure bacillary ostearthritis, which is merely a localization of a general disease. It should be accompanied by heliotherapy and climatotherapy, which improve the general condition of the patient and enable him to offer more resistance to the infection. In mild cases, especially among children, helioclimatotherapy alone is sufficient.

*Gastroduodenal Hemorrhages in Digestive Perivisceritis. M. Chiray and P. Amy.—p. 921.
Life Cycle of Eberth's Bacillus and of Paratyphoid Bacilli. P. Hauduroy.—p. 924.

Gastroduodenal Hemorrhages in Digestive Perivisceritis.—In regard to the etiology of such digestive disorders as hematemesis and melena, Chiray and Amy suggest, in addition to the commonly ascribed causes, splenomegaly, perivisceritis and disturbances in the passage of food through the colon. The pathogenesis of digestive hemorrhages concomitant with splenomegaly is complex. It is certain, however, that in such cases there is a hypertension of the splenogastric circulation, which may be caused by an intrahepatic lesion or a phlebitis of the extrahepatic portal system with the contractility of the spleen as a possible accessory cause. Facts concerning hemorrhages in perivisceritis are not nearly so well known. Digestive hemorrhages occur frequently in secondary periduodenitis with infectious conditions in the organs of the right iliac fossa. Gastritis and congestive, hemorrhagic and sometimes necrosing duodenitis are maintained and aggravated by a perivisceritis developing at the same time. The latter seems to evolve independently in spite of the removal of the infected area that produced it, while repeated interventions in these inflammatory foci serve only to aggravate the peritoneal reactions. The authors cite numerous cases of dyspeptic disorders with lowered general resistance and localized abdominal pains. In all of these, after appendectomy, adhesions occurred in the subhepatic area, followed by bleeding. Successive operations showed no ulceration. Subhepatic peritonitis increased. In such cases perivisceral complications seem to be provoked or at least favored by the first subhepatic operation. Prior to any intervention the authors find an appendectomy necessary, or, if there is no appendix, liberation of the ileocecum preceded and followed by a long rest. Of the digestive hemorrhages linked with disturbances in the passage of food through the colon, little is yet known. In two cases cited by the authors, concomitant infectious phenomena of the right iliac fossa were observed, as well as intoxication disturbances with liver disorders. They call attention to the fact that congestive duodenitis may be provoked by left colic stasis, particularly in dolichocolon.

Total Tonsillectomy: Sluder Method. G. Portmann.—p. 997.
Tuberculous Pneumonia: Anatomic and Clinical Study. P. Ameuille, R. Huguenin and P. Foulon.—p. 998.
Gallstones: Formation and Structure. A. Bergeret and J. Dumont.—p. 1002.

Amebic Abscess of Lung.—Labbé reports a case of amebic abscess of the lung with long standing refractory amebic dysentery in which he was unable to isolate the specific ameba. A rapid cure was effected by means of six daily doses of 0.8 Gm. of emetine hydrochloride.

Visceral Leukopedesis: Low Leukocyte Count During Digestion.—The numerical curve of blood leukocytes at the beginning of digestion often falls 1,500 or 2,000 cells per cubic millimeter. Its frequence is such that it should be considered from a physiologic rather than from a pathologic standpoint in the opinion of Loeper and Michaux. The leukocyte afflux is constant in the viscera during the period of digestion. It is high numerically, which accounts for the decrease in the blood leukocytes. The initial leukopenia of digestion is above all a leukopenia of displacement due to the visceral attraction of the white cells. By means of observations of patients and animals the authors found that leukopedesis may occur in the stomach, intestine, liver and kidney. Wine was the medium used to perform the experiments. Gastric, intestinal, hepatic and renal leukopedesis was noted from within one to three hours after ingestion or injection of the wine. Tubages performed on patients with gastric leukopedesis showed 1,500 leukocytes per cubic millimeter at the end of the first hour and 2,000 at the end of the second. Food introduced into the digestive tract determines a leukocytic attraction which in its turn acts as a marked leukotropic agent.

Revue de Chirurgie, Paris

68: 1-84 (Jan.-Feb.-March) 1930

*Mechanophysiotherapy and Surgical Therapeutics. E. Apostoleano.—p. 1.
Primary Tuberculosis of Patella. M. Patel and J. Marion.—p. 49.
*Encephalic Accidents After Ligature or Unilateral Resection of Internal Jugular Vein. J. Creyssel and M. Douillet.—p. 62.

Mechanophysiotherapy and Surgical Therapeutics.—Apostoleano conducted a series of experiments on horses and dogs to ascertain whether delay in cicatrization of wounds was due to overzealous treatment, especially to chemotherapy and bandaging. He found mechanophysiotherapy sufficient for the treatment of wounds. Under its action they healed more quickly and surely. Bandaging is an evil that is, however, necessary in certain well defined cases, but ordinarily the more infected a wound is, the more harmful the results produced by the dressing that covers it. Aerothermotherapy and heliotherapy are more effective healing agents than the usual dressing and antiseptic treatments.

Encephalic Accidents After Ligature or Unilateral Resection of Internal Jugular Vein.—Creyssel and Douillet report three such cases in the course of tumor operations. One case was followed by transitory disorders of the peripheral circulation, the second by brachial monoplegia, while death ensued in the third case. The authors classify such phenomena in three categories: slight, moderately serious, and fatal accidents. In the fatal case necropsy and microscopic examination showed that it was a question of a venous hypertension process. The insufficiency of the remaining jugular system after a unilateral resection accounts for the fatal venous stasis. If this insufficiency is slight, the resulting disorders are mild or transitory; if more complete, the disorders are permanent and fatal. The frequency of fatal cases is fortunately low. It seems impossible to foresee the occurrence of such accidents. When serious and alarming symptoms develop, the preferable method of checking them seems to be a local venesection, obtained by loosening the ligature of the central jugular end.

Revue Française de Pédiatrie, Paris

6: 265-423, 1930

*Creatinuria and Carbonuria. L. Garot.—p. 265.
Acidosis in Infants. S. E. Burghi.—p. 335. C'td.

Creatinuria and Carbonuria.—From the beginning of his life the nursling eliminates creatine and creatinine in variable proportions, with the latter habitually predominant. The average amount of total creatinine excretion is 24.3 mg. per kilogram of body weight in twenty-four hours. This amount of excretion is independent of the nitrogen richness of the food within the limits in which it may vary in infant dietetics. The creatinine eliminated is of exclusively endogenous origin; the creatine has a double origin: endogenous and exogenous. The exogenous fraction of creatine is variable in different patients. It is to be determined by protein inanition tests. Garot calls attention to the characteristic modifications undergone by the excretion of creatinic bodies in infantile denutrition. In cases of hypo-athrepsia of the first degree, and in a number of those of the second degree, it maintains an almost normal value with a slight tendency to decrease, the tendency bearing only on the creatine. In other cases of hypo-athrepsia of the second degree, and of athrepsia, the excretion of creatinic bodies is considerably diminished. The decrease concerns both the preformed creatinine and the creatine, but the latter predominantly. The subdivision of denutrition in nurslings into hypo-athrepsia of first and second degrees and athrepsia does not indicate the chronological order in appearance of the nutritional alterations. From the physiologic point of view, the denutrition seems to evolve in two phases, of which the second is realized only in the course of second degree hypo-athrepsia. Its appearance cannot be put into relationship with a definite percentage of weight deficiency. During the first physiologic phase of denutrition, the extent of exchanges (of which the total creatinine is a good measure) does not seem altered. In the course of the second phase there seems to be a serious decrease in thermogenesis. The almost complete disappearance of creatine in the urine in the course of the second stage of denutrition prevents considering serious hypo-athrepsia as simple inanition since progressively increasing creatinuria is the most constant evidence of nutritional deficiency. The author believes that this extensive research further weakens the opinion of those who consider creatinic excretion as proportionate to muscular mass.

Pancreatic Secretions Following Injection of Peptones. R. Carusi.—p. 344.
Pulpitis Due to Streptococcus Viridans; Endocarditis Lenta; Periarticular Fibrous Nodules. M. Scelba.—p. 353.

Functioning of Bone Marrow in Pulmonary Tuberculosis.—Gosio and di Natale endeavor to construct for each patient on the basis of clinical and laboratory observations the nature of the functioning of the bone marrow at the time of observation, and seek to determine to what extent the functioning may be due to the specific morbid factor and how far it may be dependent on other conditions. In evaluating the functional power of the bone marrow, two principal factors must be taken into account: (1) the soil on which the infection develops, which may influence diversely the type and the duration of the reaction, and (2) the fact that a given hematologic symptom may intervene at an absolutely different time from the clinical evolution and hence assume a diverse significance and importance if associated with factors that may have contributed to its causation. Neglecting these factors that delimit the significance of the hematologic examination, they considered the percentages, deriving them from the examination of 200 patients affected with the most diverse clinical types of pulmonary tuberculosis.

Heterologous Implants of Suprarenals in Rabbits. N. V. Bedarida.—p. 1017.
*Grave Syncope Due to Pneumothoracic Insufflation, Controlled by Double Intracardiac Injection of Epinephrine. G. Bonanno.—p. 1019.
Three Hundred Appendectomies Without Burial of Stump. B. Masci.—p. 1021.

Syncope Due to Pneumothoracic Insufflation, Controlled by Intracardiac Injection of Epinephrine.—Bonanno has found the endocardiac injection of a 0.1 per cent solution of epinephrine always harmless and often effective. The method is especially adapted to syncope. In diseases that cause death through profound changes in the tissues, the intracardiac injection of epinephrine is not indicated. The procedure may be employed repeatedly in the same subject with impunity. It should be applied promptly as soon as there are signs of stoppage of the heart (within ten minutes). The technic of the puncture is simple and few instruments are required. It is preferable to apply the injection to the left ventricle. The method is destined to become widely used and to render ever increasing service, for which reason it should be available to every medical practitioner.

Rivista di Clinica Medica, Florence

31: 505-556 (May 15) 1930

Pseudoleukemic Lymph Node Tuberculosis: Case. F. Schupfer.—p. 505.
*Pressure Variations in Brachial Artery Under Influence of Prolonged Compression with Arm Sphygmomanometer. F. Forti.—p. 517.
Acute Erythremic Normoblastic Myelosis with Reticulo-Endotheliosis. P. Canale.—p. 530.

Pressure in Brachial Artery Under Influence of Prolonged Compression with Sphygmomanometer.—Forti recalls that, in determining arterial pressure, in many examinees the sphygmomanometric values obtained at the first trial are modified (usually lowered) at later trials. In explanation of this fact, various factors have been invoked, some of a general and some of a local nature. The latter may act in various ways: through the reflexes produced as a result of stimulation of the compressed nerve trunks; through the influence exerted by the arm band on the walls of the artery, and, finally, by disturbances of circulation induced below the arm band by the interruption of the blood stream. In his experiments the author used the Riva-Rocci apparatus. The results of the experiments confirm the existence of pressure modifications due to the influence of the sphygmomanometer. He noted that such modifications were not only downward, as has been more commonly noted, but also upward with greater frequency than has been reported. A knowledge of these facts, he thinks, has a certain interest from a practical point of view, as it aids in the evaluation of the data of clinical and experimental studies on arterial pressure. The differences do not usually exceed from 5 to 10 mm. of mercury, but occasionally they amount to 15 and even 20 mm. The author emphasizes that it is well to take account of these possibilities in order to avoid drawing wrong inferences from erroneous observations.

Rivista di Patologia e Clin. della Tubercolosi, Bologna

4: 441-532 (June 30) 1930

Filtrable Tuberculosis Virus. A. Sega and A. Brustolon.—p. 441.
Symptoms and Pathogenesis of Total Mediastinal Hernia. F. Costanzi.—p. 458.
*Tuberculosis Diffused to Abdominothoracic Lymphatics with Lymphatic Propagation from Tracheobronchial Lymph Nodes to Lungs and Pleuras. V. de Benedetti.—p. 465.

Acoustic Theory of Physiologic Tracheobronchial Respiration. C. Minerbi.—p. 489.
Thoracic Cutaneous Telangiectasias in Tuberculous Persons. C. Alessandri.—p. 502.

Tuberculosis Diffused to Abdominothoracic Lymphatics.—De Benedetti describes a case of genital tuberculosis with invasion of the abdominothoracic lymph nodes and spread of the virus to the tracheobronchial lymph nodes and a case of diffuse pleuropulmonary tuberculosis with probably intestinal port of entry. He discusses briefly the conceptions of Costantine and of the French school on the importance of the hilus in the genesis of pulmonary tuberculosis in the adult. He regards as justified the tendency of certain modern phthisiologists to raise objections to the theory of direct infection and superinfection from the alveolus, holding that the cases reported constitute exceptional clinico-anatomic observations.

Intracutaneous Reaction to Resorcinol for Early Diagnosis of Pulmonary Tuberculosis.—Marcialis concludes that the intracutaneous reaction to resorcinol will not serve in clinical practice for the early diagnosis of pulmonary tuberculosis, not only because it gives negative results in a notable percentage of cases in which there are well founded reasons to consider the organism infected, but, above all, because the outcome is negative also in many cases in which the tuberculous infection is clinically confirmed, while the reaction is sometimes positive in cases in which no anamnestic, clinical or roentgen data point to the presence of tuberculosis.

Archivos de Cardiología y Hematología, Madrid

11: 257-304 (June) 1930

*Arterial Tension in Chronic Pulmonary Tuberculosis. C. Diez Fernández and R. Navarro Gutiérrez.—p. 257.
Effects of Zinc Phosphide on Fibrinogen Content of Blood. F. Más y Magro.—p. 266.

Arterial Tension in Chronic Pulmonary Tuberculosis.—Diez Fernández and Navarro Gutiérrez determined the arterial tension of 180 patients with chronic pulmonary tuberculosis, observed for more than one year. The patients were grouped, first, according to their age into three subgroups (less than 20 years, from 20 to 40 years and more than 40 years), secondly, according to the duration of the tuberculosis (less than one year, from one to three years and more than three years), and, thirdly, according to the anatomic and clinical forms of tuberculosis (fibrocaseous, fibrous and hilar and exudative). The authors consider that more important than the determination of the condition of the arterial tension is the determination of the modifications of the tension curve, especially when the modifications are observed over a long period of time. They present their results in tables and conclude that there is no proof that there exists a tensional difference in either arm in relation to the localization of the tuberculous lesion. It has not been proved that hypotension is more frequent in young persons than in older ones. The evolution of the arterial tension in pulmonary tuberculosis is of only relative value. It is of value only when associated with the clinical symptoms. Pneumothorax and phrenicectomy do not modify the tensional curve.

Semana Médica, Buenos Aires

37: 1545-1620 (June 19) 1930. Partial Index

Results of Nephropexy (Marion) as Observed by Pyelography. J. Salleras.—p. 1545.
*Experimental Ossification: Formation of Bone in Connective Submucous Tissue of Renal Pelvis. O. F. Mazzini.—p. 1581.
*Varicocele: Technic of Surgical Treatment. J. H Macome.—p. 1587.

Experimental Ossification.—Mazzini's experiments confirmed those of Sacerdotti and Fratin, which prove that bone is formed at the expense of the connective submucous tissue of the renal pelvis of a rabbit after a lapse of time during which a ligation of the vessels of the hilus of the kidney has been done, without any participation of the osteogenic tissues. The author ligated the pedicle of the left kidney of two rabbits. The animals were killed four months later. In one of the animals the difference between the right and left kidneys was more marked than in the other animal (10 and 2 Gm. and 13 and 5.5 Gm., respectively).

Varicocele: Technic of Surgical Treatment.—Macome says that the operations suggested by del Valle, by Ivanissevich and by Posadas for the surgical treatment of varicocele are the most simple and, if properly used, they yield the best results. The author describes the technic of the three operations. Regardless of the surgical method used, the hygienic treatment and the avoidance of venereal excesses and of constipation are important. In cases of ectasia of the anterior or large part of the venous plexus of the cord with marked ptosis of the testis, the operation of del Valle should be used. When ptosis of the testis is insignificant and the varicocele is of a funicular type and there is reflux, the operation of Ivanissevich should be preferred. When there exists visceral total ectasia of the venous plexus of the cord associated with marked ptosis of the testis, the operation of Posadas is indicated.

Siglo Médico, Madrid

85: 661-688 (June 21) 1930

*Quinine Allergy. S. Larregla.—p. 661.
Laryngotracheal Complication in Ozena: Local Application of Cajuput Oil. G. Uruñuela.—p. 664.

Allergy After Treatment with Quinine Sulphate.—Larregla reports the case of a girl, aged 16, who had influenza. Among the drugs administered was quinine sulphate. Soon afterward the temperature rose to 102.2 F. and the following day the patient had fever, headache and photophobia, with a generalized rash. The condition was considered to be an allergic reaction to quinine. The immediate suppression of the drug and the administration of calcium chloride and of a preparation of fish albumins caused the disappearance of all the symptoms, and the recovery after a few days. Idiosyncrasy to quinine was strongly suspected when the patient's history showed that one year before she had had an infection (diagnosed as intestinal infection) in which quinine was administered. During this infection the patient had developed a protracted typical dermic exfoliation associated with edema, vomiting, constant and high fever, albuminuria and great emaciation. Some time after recovery the reaction to quinine was tested. A scratch was made on each forearm. In one of the scratches a drop of physiologic solution of sodium chloride was placed and in the other a drop of quinine sulphate. The first scratch remained unchanged whereas the second scratch after one hour presented a marked redness, which persisted for several days. The father of the patient had an idiosyncrasy to tincture of iodine. The author advises that one have in mind such cases of allergic reaction when this condition appears during the evolution of a disease in which chemotherapy is used.

85: 689-716 (June 28) 1930

*Problems Related to Babinski Reflex. C. Juarros.—p. 689.
Treatment of Imminent Abortion. J. Lacasa Val.—p. 694.

Problems Related to Babinski Reflex.—To prove the diagnostic value of the Babinski reflex, Juarros made observations in three groups of children: 200 new-born infants during the first hour of life; 150 backward children of a psychiatric school of abnormal children (with oligophrenia, but without focal or cerebral lesions); and 200 infants aged 1 week. He concludes that there are two types of Babinski reflex, the physiologic reflex and that of a peripheral origin. Whenever a positive Babinski reflex is elicited, one should think of the possibility that the reflex may have a peripheral origin. The physiologic Babinski reflex may exist in normal new-born infants with no disturbances of the nervous system. Its presence in them, however, is not constant. The presence of the reflex during childhood is not an indication of mental backwardness. It is probable that the so-called physiologic Babinski reflex is governed by factors similar to those which govern the reflex of peripheral origin; that is, the presence of a motor disequilibrium between the flexor and extensor muscles. The disequilibrium may have been determined during intra-uterine life, by the situation of the toes of the fetus in the uterus. The upright position does not play a part in the production of the physiologic Babinski reflex, which is not caused by an incomplete development of the pyramidal tract or by a predominant influence of extrapyramidal origin. The method and conditions under which the reflex is elicited may have an influence on its presence or absence. The diagnostic value of the Babinski reflex should be revised. The reflex may appear in some patients without lesions of the pyramidal tract and may be absent in others in whom pyramidal disturbances are obvious.

Nephrogenous Scoliosis.—Blumensaat and Nestmann call attention to the fact that in most cases of kidney disease there results some scoliosis of the lumbar segment of the spinal column. In cases of renal calculus the curve is convex to the stone; in hydronephrosis, pyonephrosis, pyelitis, tuberculosis, paranephritis and mobile kidney it is concave to the lesion. In cases of tumor the direction of the scoliosis is variable. The authors prefer the term nephrogenous scoliosis to the older term nephritis scoliosis. In the stone cases it is the result of a protective action; in the hydronephrosis cases it is a mechanical result and in the remaining cases it is caused by the contraction of the muscles on the diseased side. These observations are believed to have not only diagnostic but also therapeutic value.

Radical Operation for Carcinoma of Rectum.—Dannheisser analyzes 180 cases. Ninety-nine were not operable. Treatment by radiation and by colostomy was given and the patients succumbed in from six to twelve months after the institution of the treatment. The remaining 81 patients were subjected to operation—27 amputations with sacral anus; 37 sacral resections; 6 Hochenegg operations; 11 abdominosacral resections. Twenty-four patients died shortly after the conclusion of the operation; 20 after leaving the hospital (16 from a recurrence); 37 are living, 7 still under observation, 3 with a recurrence. Cure after three years was observed in 40 per cent; after five years in 46 per cent. Of the healed sacral resection cases, 77 per cent of the patients have continence; 10 per cent have an intestinal fistula. From every point of view, the author prefers sacral resection to any other operative procedure.

Surgical Treatment of Habitual Dislocation of Shoulder.—Oetiker reviews the results of eleven cases in which he operated. He prefers plication of the capsule when no other lesions than the dislocation are present. He presents a splendid review of all such cases recorded in the literature since 1918.

Mixed Tumors of Scalp.—Erb reports a case of tumor of the scalp over the right parietal bone apparently caused by a trauma—a fall from a ladder. Histologic examination showed that it contained mucous membrane, cartilage, bone and numerous epithelial elements—adenomatous, cylindromatous and carcinomatous. Clinically, the tumor seemed to be of the benign variety. Some neuro-epithelial elements were also found. The author assumes that an embryologic rest consisting of epithelium and periosteum was the point of origin of the tumor.

Grossich's Method of Iodine Disinfection of Skin.—After twenty-two years' experience with this method, Curri concludes that it is far superior to any other method. He has employed it in 20,000 operations with invariably good results. He feels that the "urge" to discover newer and, possibly, better methods has led to failure to appreciate this method at its true value.

Value of Scarlet Fever Vaccination.—Schottmüller describes a scarlet fever endemic in a children's home in Hamburg, which was checked by vaccination. He points out that prophylactic active immunization with scarlet fever streptococcus toxin was first successfully employed by Gabritschewsky. Passive immunization with scarlet fever streptococcus immune serum gives immediate protection but is effective for only two weeks, whereas prophylactic active immunization becomes effective only after several weeks but after that gives protection for about two years or longer. By employing both these methods the spread of the endemic was prevented. The efficacy of the vaccination was also proved by Dick tests. In the conclusion the author states that immunity against the scarlet fever streptococcus, which is produced either actively or passively, protects primarily against an outbreak of the disease. But even during the beginning or toxic stage of scarlet fever the immune serum is effective. However, the second stage of the disease is not influenced by vaccination. The efficacy of active and passive immunization with products of the scarlet fever streptococcus proves that this specific streptococcus is the only cause of the disease.

Double-Barreled Laryngeal Intubation Instrument for Filling Lung with Contrast Medium.—The double-barreled laryngeal intubation instrument recommended by Baisch is a modification of O'Dwyer's tube. Following a description of the construction of the apparatus and the technic of its introduction, several case reports are given and illustrated with roentgenograms. Iodized sesame oil 40 per cent is the contrast medium most commonly used. The advantages of the double-barreled laryngeal intubation instrument are summed up as follows: 1. It involves no danger when used by the physician who knows the technic of intubation. 2. It is simple and the aid of a specially trained laryngologist is not necessary. 3. In children the filling of the lung by means of the double-barreled laryngeal tubes is the method of choice.

Experimental Study of Blood Extravasated into Body Cavities.—The blood examined by Heusser and Stössel was taken from the peritoneal cavity of rabbits. It is said that macroscopically it appeared to be normal. Slight degrees of hemolysis could not be detected with the eye; high degrees were easily detected. Such blood contains many clots. The blood that is obtained by filtration of the whole mass should not, on the whole, clot further, but it cannot be stated absolutely that this is the case, because cases of clotting are on record. Hence, care should be taken in this regard when such blood is reinjected into the circulation. It was also determined definitely that, while blood was flowing into a body cavity, resorption of the exudate was also taking place. The corpuscular elements are greatly diminished in extravasated blood; likewise the number of leukocytes and the hemoglobin. The resistance of the erythrocytes is diminished considerably, a point to be borne in mind when one wishes to reinject blood extravasated into a body cavity. This procedure is in need of much more investigation before it can be stated definitely that it has a place in therapeutics.

What Happens to Suture Material?—Christ has made a histologic and bacteriologic study of the fate of various kinds of suture material in several hundred aseptic operations for goiter, hernia and loose joint cartilages. He found that every kind of material yielded similar results depending entirely on its asepsis, the amount of suture material embedded, the possibility of secondary infection, the local tissue reactions and the general reactions of the individual. Selection of suture material should be made on the basis of how easily it can be sterilized and handled; its strength and elasticity. Silk and linen is the equal of any suture material, and preferable to any other. So-called suture infections may be prevented by a perfect aseptic operative technic; complete asepsis of the material to be used; absence of infective foci in the tissues surrounding the field of operation and "atraumatic" postoperative treatment. This is especially applicable to operations on the thyroid. Suture of the capsule should be made to obviate the flow of secretion into the wound afterward, and prompt evacuation by puncture of hematomas, serous effusions and thyroid secretions should be performed.

Postoperative and Experimental Tetany.—Christ asserts that tetany is a general intoxication. The appearance in the blood of noxious substances the result of faulty metabolism leads to a lowering of the blood calcium and that is the direct cause of tetany. The severity of the tetany is dependent on the fall of the calcium curve. Therefore, the author recommends that, in cases of human tetany, viosterol (vitamin D) be administered in sufficient doses. Acute and chronic forms also call for the administration of organ extracts and calcium. In the acute cases it is important to give large doses of calcium. Blood transfusion is indicated. Milk diet, vegetables and the avoidance of meat foods is essential. Frequent examinations of the calcium curve are of great value in regulating the treatment.

Tuberculosis of Tongue. — This review of 217 cases by Nicolas shows that tuberculosis of the tongue occurs more often than does tuberculosis of any other structure of the mouth, including the tonsils. The left side is the usual seat of the disease; men are affected more often than women, in the ratio of about six to one. The disease is always secondary, the infection coming through the blood or lymph stream. Primary, exogenous infection is exceedingly rare. The only treatment is excision and cauterization. The prognosis is dependent on the general condition of the patient, the stage of the primary focus, usually in the lung, and the course of the primary disease.

Experimental Production of Bladder Tumors. — By means of inhalation of aromatic amino preparations, especially naphthylamine, Schär succeeded in producing experimental carcinomas of the bladder.

Primary Tuberculosis of Spleen.—Cynman reports a case of primary tuberculosis of the spleen, without a tuberculous focus elsewhere in the body, in which the spleen was removed. Three and a half years later there was no evidence of tuberculosis anywhere.

Acute Dilatation of Stomach.—Petitpierre calls attention to the fact that not only may dilatation of the stomach occur after operation, combined with general anesthesia, but that it is not entirely an infrequent occurrence in cases of acute infectious disease. He cites a case of pneumonia in which this complication was noted on the fifth day of the disease. The symptoms led to the suspicion that pneumococcus peritonitis or a perforated appendix was responsible. Neither was found at operation; instead the stomach was greatly enlarged and dilated. It was punctured and about 2.5 liters of fluid was removed. The patient died the following day.

Tumor Formation in Hernial Sac. — In Richard's case numerous adenocarcinomatous masses were found on the wall of the sac and the serosa of the portion of the sigmoid that was lying in the sac. The patient died four months after the operation in a state of cachexia but free from symptoms of obstruction of the intestinal tract. A case of primary fibroma of the mesentery contained in a hernial sac is also reported.

So-Called Acetonemic Vomiting in Children.—Brückner points out that vomiting is a frequent symptom in children. There is hardly any children's disease during which it may not occur. However, small children and those of early school age occasionally show a pathologic condition in which vomiting is the main symptom. This so-called acetonemic vomiting is most frequent in neuropathic children aged between 3 and 7 years. In most cases, attacks of vomiting recur periodically. They develop after an indisposition lasting several days or develop suddenly after a psychic shock. The vomit consists at first of fragments of food and later of a greenish watery substance. The vomiting increases when food intake is attempted, but it also continues when the child does not eat. The children lose weight rapidly, dark rings show around the eyes, the tongue and skin are dry, and the turgor is reduced. The respired air has the odor of fruit. The abdomen is flat, the liver does not show marked enlargement and the temperature may show a slight increase, but the pulse is usually normal. The quantity of urine is reduced and it contains acetone, beta-oxybutyric acid and diacetic acid but neither protein nor sugar. The elimination of ammonia is increased and the alkali reserve in the blood plasma is reduced as a sign of existing acidosis. The blood picture does not show characteristic changes. The sensation of pressure and abdominal pains are muscular pains caused by the effort of vomiting. After two or three days the vomiting and the acetonuria decrease and the appetite increases. The opinions concerning the etiology of the disorder are still divided. The author reviews several theories and comes to the conclusion that it is a neuropathic disorder, probably due to a disturbance in the nervous regulatory apparatus for the carbohydrate metabolism. In the diagnosis of the condition the differentiation from appendicitis and from basilar meningitis is of primary importance. The vomiting and the odor of the respirated air are decisive for the diagnosis. In acetonemic vomiting the abdomen is flat and, although painful, a special point of pressure and muscular tension are absent. The voidance of urine and the lifting of the right leg is likewise painless during acetonemic vomiting. The blood picture may be an aid for the differential diagnosis, in that leukocytosis is absent in acetonemic vomiting. For the diagnosis of basilar meningitis the development of rigidity of the neck, changes in the pulse and Brudzinski's and

Kernig's signs should be awaited. For the treatment of acetonemic vomiting the author recommends the administration of carbohydrates in the form of sweetened fluids. As soon as the vomiting stops it is advisable to give a paplike diet rich in sugar. If the vomiting and the dehydration are especially severe, dextrose solution should be administered either in the form of enemas or by subcutaneous or intravenous injection.

Perforation of Ulcerated Colon Caused by Contrast Medium.—That roentgenoscopic examination of the intestine with the aid of a contrast medium is not an entirely harmless procedure is proved by Kaulich. He reports the clinical history of a woman, aged 57. An operation revealed that a portion of the barium preparation, which twenty-seven days previously had been administered by mouth, had developed into a fecal concretion of about the size of a fist. It was lodged in the sigmoid flexure and had caused symptoms of intestinal obstruction. When a tumor of the colon was suspected, roentgenoscopic examination was again thought necessary and the barium preparation was introduced through the rectum. During the administration of the barium enema the ulcerated intestinal wall perforated above the fecal concretion, as a result of the increased pressure due to tenesmus. Through the opening of the perforation the barium preparation entered the abdominal cavity. An operation was performed immediately. A preternatural anus was made and the abdomen was irrigated. In order to prevent such accidents the author stresses the following points: 1. It is necessary that the anamnesis and the status of the patient be known before the rectal administration of the contrast medium is begun. 2. In cases of bleeding ulcer of the colon a clyster examination is not advisable. 3. The quantity of the contrast medium should not be more than 1 liter. 4. The filling of the colon should be done from a height of not more than 50 cm. 5. Whenever the patient complains of increasing pains or pressure, the administration of the contrast medium should be discontinued.

*Congenital Stenosis of Digestive Tract. B. E. J. H. Becking.—p. 731.
Rickets and Ergosterol. N. Speelman.—p. 750.

Congenital Stenosis of Digestive Tract. — Becking describes three cases of congenital stenosis of the digestive tract recently observed in infants at the Kinderziekenhuis in Utrecht. In the first infant the physician found in the right abdomen a suspicious resistance and sent the child to Utrecht with the tentative diagnosis "invagination." The peritoneum was opened and the mass of the intestine seemed incoercible. There was fluid in the abdomen and the intestine was exceedingly red. No invagination was found. The swelling was felt at first, but afterward it could not be found. The abdomen was closed. The child died the next morning. The surgeon broke open the sutures and found a large portion of the small intestine in a state of severe hemorrhagic inflammation. Above Bauhin's valve, in the ileum there was a highly stenosed portion, about 2 inches long. At one point, the intestine was almost broken through. The mystery of the swelling in the right abdomen was not solved. The second infant, when 14 days old, became highly constipated and had spells of vomiting. The child died six days after admission to the hospital. Necropsy revealed a moderate dilatation of both ureters and a diverticulum of the duodenum. Not only the stomach but also the first portion of the duodenum were highly inflamed, and where the duodenum became thin there was a sort of valve that made passage of intestinal contents to the stomach easy, whereas passage of food from the stomach to the intestine was difficult. Under certain conditions, food could find its way through, which explains the regular, normal stools. In the third infant, vomiting spells set in after six weeks. Changing the diet frequently, the mother worried along with the child until it was 9 months of age. The child was admitted to a hospital and a roentgenogram revealed a stenosis of the esophagus about 2 cm. above the diaphragm. With an esophagoscope the examiner discovered 20 cm. from the teeth a diverticulum of the esophagus, with an opening the size of the head of a pin. By making a gastric fistula (Witzel method) it became possible to feed the child better. But, at the end of seven weeks, the child had gained only 1,140 Gm. in weight. The hemoglobin content of the blood had advanced from 38 to 51, but he still looked pale and poorly. Five months after the operation the weight had come up from 6,430 Gm. to 8,450 Gm. The child is still living, but it is impossible to give it through the slender tube all the food it needs. The author discusses at length congenital diverticula and those arising post partum.

*Epidemiology of Poliomyelitis in the Netherlands. J. T. Terburgh.—p. 3528.
Poliomyelitis Anterior Acuta. F. S. van Bouwdijk Bastiaanse.—p. 3544.

Epidemiology of Poliomyelitis in the Netherlands.—Terburgh reports the incidence and the mortality of poliomyelitis in the Netherlands during the period 1924-1929. During the first five years the number of cases reported did not exceed 75, but in 1929 it was 507 with a mortality of 15.6 per cent. During the first years after cases of poliomyelitis became notifiable (Aug. 30, 1923), there were no doubt more cases than the statistics show. The number of deaths is evidently more complete than the number of cases. The mortality rate of 15.6 per cent recorded for 1929 is not excessively high—not much higher than the average mortality reported by the health section of the League of Nations (from 12 to 13 per cent).

*Sarcoma Following Roentgen Treatment of Tuberculosis of Joints. B. Backlund.—p. 554.
Effect of Psychic Condition on Calcium Content of Blood. M. C. *Ehrström.—p. 571.*

Liver Diet and Reticulocyte Reaction in Simple Anemia.—Wahlberg reports nineteen cases of simple anemia. In nine out of fifteen liver therapy was followed by improvement, but in only three out of thirteen cases was the effect superior to that of arsenic and iron, while seven reacted more favorably to arsenic and iron. The comparatively good effect of liver therapy in chronic posthemorrhagic anemias and other chronic anemias with weak regenerative power, noted also by Pal, Vaughan and Gram, point to a stimulation of regeneration in certain cases of simple anemia, although in far less degree than in pernicious anemia. In simple anemias also the reticulocyte reaction is of practical value as the first sign of beginning improvement.

Coxa Vara and Internal Secretion.—Two of Nyberg's cases of coxa vara of adolescence showed no evidence of abnormality of internal secretion as a basis for the bilateral pathologic condition, but the third was apparently a typical instance of adiposogenital dystrophy. Tests of the basal metabolism, calcium content of the blood and renal function gave normal values; a dextrose tolerance test revealed a pathologic blood sugar curve.

Sarcoma Following Roentgen Treatment of Tuberculosis of Joints.—In Backlund's patient with disease of the knee joint, diagnosed as tuberculous, since her eleventh year, intensive irradiation for two years, begun at the age of 34, resulted in considerable improvement for five years, when the symptoms became increasingly aggravated. These were atrophy of the skin and telangiectasis and on the inner side of the knee a softer, fluctuating portion, which was excised. Microscopic examination disclosed recent spongy connective tissue, osteoid tissue, concentrically arranged hyalin formation, and spindle cell sarcoma. Removal of a pea-sized tumor that had developed in the same place ten months later was followed after seven months by a second tumor, necessitating radical intervention. Both were spindle cell sarcomas. After another six months amputation was done, as the whole medial portion of the knee was destroyed by a spindle cell sarcoma. Half a year later there were signs of pulmonary metastases. The case was found to agree with eleven others in the literature in which sarcomatous changes after roentgen treatment are ascribed to roentgen injury, although the tuberculosis cannot be excluded as a contributing factor.

THE DIAGNOSIS OF CANCER*

FRANCIS CARTER WOOD, M.D.
NEW YORK

The extensive education of the lay public which has been conducted in the past fifteen years by the American Society for the Control of Cancer has created a situation not without interest to the medical profession as a whole. The fact is that while it is perfectly possible to have the lay public absorb a certain amount of information concerning the symptoms of cancer, after such absorption has taken place and the desired reaction occurred the profession is not in a position, speaking generally, to render efficient service to those who apply for it. In other words, the medical profession as a whole is not yet prepared accurately to diagnose the disease which it is called on to treat, at a stage which permits of effective therapeutic attack, nor are all surgeons or radiologists prepared to offer the proper therapy.[1]

This failure is not confined to the internal group of neoplasms in which the diagnosis is in many instances extremely difficult, if not absolutely impossible and for which no effective treatment exists at present, but it concerns tumors of the breast, the cervix, the lower part of the rectum, and the oral cavity, where easy visual and digital access makes the diagnosis of cancer relatively simple and cure possible. In discussing these matters, it is not intended to criticize the practitioner of the small town or rural districts, who often has but little opportunity to observe cancers clinically. He may not see a cancer of the tongue once in two or three years and may therefore not be quite so accurate in his diagnosis as his city colleague who sees more cases; but on the whole, he is often better than they. It is rather the city man who with fair clinical experience still does not know enough to refer for immediate surgical or radiation treatment a hard nodule in the tongue. One of the leading dermatologists in the United States treated a cancer of the tongue for nearly a year with arsphenamine simply because the patient had a four-plus Wassermann reaction. Meantime the nodes had become extensively involved and when finally a diagnosis was made the patient was absolutely beyond hope. And yet no physician in the United States could have had greater experience. He was simply asleep. The late diagnosis of neoplasms of the cervix and the rectum is the common experience of every consultant, and even in the breast only some 50 per cent are operable on hospital admission, though frequently these patients have seen one or more physicians six months or a year previously.

The facts are at present that at least half of the malignant tumors that occur are so inaccessible that an early diagnosis can in no sense be made, and in addition even the accessible tumors are so rarely diagnosed in the early stages that only about 20 per cent of all types of accessible cancer, even in the large cities, are susceptible of operative treatment with probability of cure. A small percentage of the inoperable cases are available for curative radiation therapy, the groups effectively treated by radiation being chiefly cancers of the skin and the uterine cervix.

However, as already said, the educational campaign has been extremely effective in stirring up the population, at least in the larger centers, and as a result surgeons and radiologists are now asked to diagnose and to treat tumors in a stage much earlier than they were seen a few years past. This may be said in full knowledge of the fact that papers have been published arguing that publicity campaigns in certain localities, at least, have had no effect in shortening the period between the discovery of the tumor and the consultation with a physician.[2] One needs only to turn to the papers of Georg Winter of Königsberg, the originator of the idea of popular cancer education, to see that, if teaching is done in the proper way, remarkable benefits can be obtained by such lay instruction.

As a tumor which is easily diagnosticated by the classic textbook symptoms is in most instances already beyond any possibility of permanent relief, and as those in which effective intervention may be expected to offer cure are often in the stage in which the clinical diagnosis cannot be made with certainty, it is evident that the pathologist is assuming a position of importance which he has not held since tumor diagnosis began. Most of the successful operations on cancer are exploratory in principle; that is, a surgeon may not be certain at the time of his operation whether he is dealing with a malignant or a benign growth, or even an inflammatory lesion. The proper thing to do in this situation varies with the site of the growth. If the tumor is in the breast, an exploratory operation and removal of the tumor which can be immediately examined by the pathologist by frozen section will furnish the surgeon the guidance for the necessary extent of the operation. Many women will refuse a mastectomy and will accept the idea of an exploratory operation with frozen section diagnosis of the tumor, followed with either a partial restoration of the gland to normal or a radical mastectomy if the lesion warrants. These patients do not have to be told after they come out of the anesthesia what they have had. Such pathologic control is also important in stemming the present attitude of some surgeons that the breast of any woman over 35 containing a few nodules should be promptly removed in toto. This attitude is in harmony with the old principle, which some can remember from the surgical days of the early nineties, of removing by hysterectomy all of the internal female generative organs for almost any symptom whatever.

---

* Read before the Section on Pathology and Physiology at the Eighty-First Annual Session of the American Medical Association, Detroit, June 25, 1930.

[1] Ewing, James; Greenough, R. B., and Gerster, J. C. A: The Medical Service Available for Cancer Patients in the United States, J. A. M. A. 93:165-169 (July 20) 1929.

[2] Reimann and Safford: Rep. Internat. Cancer Conference, London, 1928, p. 562.

The procedure in the mouth and tongue is somewhat different. Here it is necessary often on account of the small size of the fragments that can be removed for diagnosis not to waste valuable material in making frozen sections but to take time to embed and properly section the biopsy fragment. This need not take more than three days, and during that time there is but little chance of a metastasis. The diagnosis is then definite; the surgeon can plan his operation at leisure and with full realization of the difficulties which he has to surmount. He will also have the satisfaction of not adding to the collection of tuberculous or syphilitic tongues which adorn the shelves of pathologic laboratories.

Many of the earlier tumors of the gastro-intestinal tract, gallbladder and ovaries are also found in the course of exploratory operations and require microscopic examination to determine their nature.

The question of frozen section diagnosis has been much discussed. Some dogmatic authorities reject the method entirely. Those who have been in the habit of doing these sections for many years will, I think, be prepared to acknowledge that in the vast majority of cases the diagnosis can be made from the frozen section just as well as from the thinnest and most perfectly stained paraffin preparation. In all cases, the diagnosis, whether on frozen or embedded material, rises no higher than the intelligence of the pathologist and the breadth of his experience. On the other hand, the knowledge of tumors has run considerably ahead of the general routine training in pathology, and unforgivable errors in diagnosis are all too frequent, even from the best equipped institutions.

The opportunities for training pathologists are not particularly good at present. Ordinary morphologic pathology is regarded as rather old-fashioned. Many pathologists quite properly prefer to experiment on a few dogs or cats, to see whether they can produce renal, hepatic, gastric or cardiac lesions, and then to study the chemical or pathologic results, than to sit down and make careful morphologic studies of tissues in order that they may help a surgeon save the life of a human being. Pathology today is suffering also from the fact that there is no financial or clinical future for a hospital pathologist. He may work faithfully for a few years, but it is almost mathematically certain that when an appointment is made on the surgical or medical staff of the hospital it will be some one who may have had a wide clinical experience but knows little or no pathology. The surgeon who is appointed is apt to have spent some years in the dissecting room, where his time was largely wasted in learning the names of things he will cut through when he operates instead of studying pathology and bacteriology. The internist will have a vast knowledge of proprietary drugs which benefit his patients but little. If the system could only be introduced in America of appointing no one to a staff position in a hospital who has not had at least one laboratory year in autopsy and microscopic tissue diagnosis, medicine would quickly show a remarkable improvement.

If, then, there is no future for the pathologist in these days of difficult living, why should any one go into pathology? That is the reason why the desks of professors of pathology are cumbered with appeals for pathologists for various hospitals when none are available, and why some small hospitals employ technicians to make their diagnoses with lamentable results. The only solution is to offer clinical advancement to those who desire it. Then the better type of physician would be willing to do pathology for a few years. This is now not always the case. If the pathologist in the future is to make frozen sections and assume responsibility for extensive surgical procedures with a clear conscience, he must be better trained on tumors than he now is. Some half-hearted efforts have been made to remedy the situation by various collections of slides and specimens in Chicago, Philadelphia and elsewhere, but the pathologist who is working in some hospital in a midwestern country town on a salary of $1,000 a year will scarcely be able to go to Chicago or Philadelphia or Boston to study sets of slides. A far more intelligent thing would be to have purchasable for a moderate sum a complete set of slides, both of autopsy and of surgical pathologic lesions, illustrating all the ordinary conditions which are apt to occur, accompanied by detailed histories. The success of Cabot's books has shown the need of something of this sort. If such a book of histories of cancer patients could be accompanied by the slides to illustrate the pathologic anatomy of tumors, the skill of pathologists would, I think, rise with considerable rapidity.

Not only is the pathologist of the future to be called on to say whether a tumor is malignant or benign, he is to be called on to state its degree of malignancy and whether or not it is radiosensitive. Whether he can ever achieve any certainty in all these aspects of prophecy is very questionable. In diagnosis, yes, almost always; in prognosis, not. No one can make a prognosis from a section except in certain well recognized groups. Lymphosarcoma is one, but I have seen slides of growths which were typical lymphosarcomas in cases in which the patient is alive some ten years later, without treatment in one instance; with a very moderate amount of irradiation in another. Though every one knows that in general a lymphosarcoma is a radiosensitive growth, yet the prognosis is almost invariably fatal. The number of cures in anything except the intestinal group is minimal, and these are cured only because they give obstructive symptoms early while the process is local. While the pure lymphosarcomas are rather sensitive to irradiation, their cousins, the reticulum cell sarcomas of the nodes, are as a rule extremely resistant. These tumors coming from the same organ exhibit entirely different biologic qualities which could not have been prognosticated from the slide.

It is always to be remembered that radiation therapy makes an assumption as to the biology of the tumor. When physicians advise such treatment they mean either that the patient is hopeless from a surgical aspect and that therefore from the point of view of palliation radiation may be given, or they mean that the tumor is radiosensitive and therefore can be completely destroyed. No pathologist can tell from a slide the difference between the two except in a very general way. If at one end the lymphosarcoma under discussion is considered and at the other tumors containing osteoid and cartilaginous tissues, the assumption is safe that the latter tumor will resist irradiation. The same assumption can be made if the neoplasm is pigmented. Between these two extremes is a broad class of neoplasms, say the carcinomas of one site such as the lip, tongue or breast, which it is true can be thrown into morphologic groups roughly correlated in their biologic qualities; but to say, as I have been told by a surgeon, that because some pathologist had grouped an epithelioma of the tongue as belonging to group 2, therefore the epithelioma should be curable by irradiation, is nonsense. This particular tumor was recommended for therapy, recurred promptly, and was entirely resistant to radiation—an effective proof of the uselessness of a certain type of grading.

The grading question also is complicated by the fact that it may be valid for surgery and invalid for irradiation, or that one type of carcinoma may have a good prognosis surgically, and be absolutely resistant to irradiation. For, after all, prognosis, as Lee[3] has shown for the breast, depends on many things—the position of the growth, its relations to the blood vessels, its lymphatic connections, its size in some cases, and finally, also, the dimensions of the tumor cells, wholly independent of their growth rate. So is seen the paradox of a huge tumor of the breast with large cells being less malignant clinically than the small cell scirrhous carcinoma in which the nodes are extensively involved before the primary tumor is recognized. The same paradox is seen in the cervix to which Healy[4] has called attention, that the squamous cell tumors which are favorable for surgical operation are the least favorable as regards irradiation. The favorable cases for irradiation are those neoplasms which are atypical, which show marked anaplasia and a tendency to invade the parametria early—in other words, possess the exact qualities that make surgery ineffective. Here again the pathologist bears a heavy burden, for he is asked to decide between surgery and irradiation on the basis of the tumor group. Malignancy, it should be remembered, is a clinical phenomenon, not a morphologic one.

It is evident from what has been said that in the near future both the clinician and the pathologist must be much better trained in the diagnosis of tumors than they are at present. The machinery for such training has not yet been developed. There are few places where the pathologist can obtain a broad fundamental training in tumor diagnosis. Nor can he buy sets of slides such as I have mentioned. He is usually not a welcome guest in the busy laboratories of those other pathologists who have abundant material but are poorly paid and overworked. In addition, he will have no assurance that if he does fit himself he will ever escape from the treadmill of routine laboratory work. There are some men fortunately fitted mentally or financially who are happy to devote their lives to this somewhat thankless task. But until it is recognized that the pathologist knows more about disease than most of the clinicians who outrank him in his hospital, and until advancement to the staff is only through the laboratory, as it is in Germany, there will still be too few pathologists. When there were 165 medical colleges there were just that many professors of pathology, and now the medical schools have fallen to such a point that the supply needed is small.

To turn to the physician: He can be trained only by seeing patients. Cancer patients form only about 3 or 4 per cent of the admissions to a general hospital. Therefore at any one time in such a hospital there are only a few patients with tumors for teaching purposes. A better place is the radiotherapeutic department, but this contains a large number of those who have been operated on and therefore the instructive diagnosis of the early stages cannot be offered. The solution of the problem will be found only when either the community or the medical profession realizes the absolute necessity of concentrating a large number of cancer cases in institutions in order that research and education can go hand in hand with the best therapy. The physician must train himself in the reading of roentgenograms, in the use of the instruments for inspection of the accessible internal regions, such as the eye, the throat and the larynx, and especially in the use of the sigmoidoscope and even the cystoscope. So far appeals for cancer institutes have fallen on rather stony ground, but there is no question that unless the profession takes the step the public will. There are hospitals for women, hospitals for children, hospitals for the mentally diseased, hospitals for patients with eye, ear, nose and throat trouble, yet when anybody suggests a cancer hospital the surgical profession rises *en masse* and says that cancer is best treated in the wards of a general hospital; in other words, that the man who operates on one carcinoma of the rectum a year is superior in skill to the man who may operate on fifty. But the only way to get the fifty is to concentrate the material in one hospital, or in a part of one hospital, and give it to that individual whose interest covers the particular anatomic field mentioned.

The moment such institutions are established throughout the country, as they will be in time, it will be possible for the man who wants to know something of the pathology of tumors to go and see his material in the wards, where the diagnosis can be made clinically, and also to follow the case to the operating room or to the radiotherapeutic department, to see the treatment, study the material obtained both from the operating room and from autopsies, and to learn to do his own frozen sections. He must, as a pathologist, learn to say "I don't know" when called on to make a vital decision which cannot be made from the material under examination; learn, in other words, to be a good pathologist, and therefore an important member of his hospital staff. At the same time the clinician can see in a short time the methods of diagnosis and treatment, and also see autopsies on cancer patients. Both of these men will quickly learn the inadequacy of much cancer treatment, chiefly because it is too late. They may not have the opportunity of preventing the removal of the tonsils for asthma from a small boy whose leg had been amputated for sarcoma some months previous and whose lungs were full of tumor. That does occur, though not often; but they will realize that many of the cases of cancer which are apparently favorable at the time of examination will be found on operation or irradiation to present extensive growths entirely unsuspected. They will learn not to treat a carcinoma of the cervix with large quantities of radium when supraclavicular invasion has already occurred. They will learn that a good surgeon does not operate on a carcinoma of the stomach when a Virchow's node exists above the clavicle, that he does not amputate a leg for sarcoma until the lung and bony system have been shown to be free from metastases, that a competent physician does not treat a child for rheumatism until a roentgenogram has demonstrated the absence of a bone sarcoma, nor administer medicine to cure sciatica in a woman who has had her breast amputated. They will learn the regrettable fact that irradiation sufficient to destroy all the cells of a tumor can rarely be put through the human skin without such damage as is irreparable. They will learn the limitations of the treatment of the epithelial tumors of the face and of the cervix, which are the most favorable fields for irradiation. They will also learn the wide range of palliation which can be accomplished by irradiation methods, either alone or combined with surgery, but they will see that palliation, however valuable, is of but short duration in most instances. In other words, the pathologist and the clinician will learn both the natural history of cancer and its diagnosis, and will realize that at present its treatment, to be effective, must be accomplished at so early a stage that even when the growth is in a favorable site it will often tax the diagnostic ability both of the clinical diagnostician and of the expert with the microscope.

It is useless to educate the public unless the profession can meet the demands so stimulated, and the profession cannot do so unless the facilities both for undergraduate and for postgraduate instruction are developed far beyond their present status. Even if this development takes place, it will be useless unless the profession sees its opportunity and uses it to the full. Then and only then will there be any real control of the cancer situation.

THE RESULTS OF MEDICAL TREATMENT OF PEPTIC ULCER *

RALPH C. BROWN, M.D.
CHICAGO

Prior to 1915, when Sippy[1] published his first paper on the medical treatment of ulcer, the forms of treatment in general use were chiefly of the Lenhartz type, a therapy based on bland foods, bed rest, hot fomentations and minimal doses of alkalis. Sippy became convinced that greater efficiency in treatment could be achieved by clearly recognizing the important influence of the digestive action of gastric juice on the unprotected raw surface of a gastric or duodenal ulcer. He believed that the peculiar tendency to great chronicity displayed by these lesions was due to the chemical action on the exposed surface of the ulcer of the powerful proteolytic gastric juice and advanced the theory that the healing of peptic ulcer could best be achieved by elimination of this deleterious chemical digestive action, an effect to be secured by complete neutralization of free hydrochloric acid in the gastric content from breakfast until bedtime, with special emphasis on the control of any existing hypersecretion during the night hours.

The application of this theory resulted in the hourly feeding schedule and the intensive use of alkalis of various types.

In the years that have elapsed, during which the general value of this manner of treatment has gained widespread recognition, two facts have emerged from continuous clinical experience with ulcer-bearing individuals. The first to be noted is the comforting certainty that by far the greater proportion of gastric and duodenal ulcers can be healed by proper medical measures. The second fact—less pleasant to dwell on but of vital importance to every ulcer-bearing person—is that these lesions tend to recur and do recur in a large percentage of patients, either at the original site or, as frequently happens, in a different area of the stomach or duodenum. These frequent recurrences have not only emphasized our essential lack of basic knowledge regarding the cause of peptic ulcer but have made clear the probability that some unknown constitutional factor plays an important rôle in the etiology. The time may soon arrive when we shall clearly recognize that a gastric or duodenal ulcer is the very troublesome local manifestation of a deeply seated disorder. More detailed questioning regarding family histories reveals a remarkable familial incidence of ulcer, suggestive evidence in support of such a constitutional factor.[2]

To determine the ultimate effectiveness of the Sippy type of treatment for peptic ulcer, a survey has been made of all cases treated by Dr. Sippy and myself at the Presbyterian Hospital from 1912 to 1927 inclusive. The report also includes 167 cases from the services of Dr. L. C. Gatewood and Dr. D. P. Abbott, former associates. In this study, no selection of cases was made. Great care was taken, however, to exclude cases, especially from the earlier years, in which the diagnosis was based on inconclusive evidence.

During March and April of this year letters and questionnaires were addressed to 1,900 patients, and more than 1,200 replies were received. The purpose of this survey is to report the present status of this group of ulcer patients regarding whose fate we have recorded information. The series I am reporting comprises a total of 1,224 cases. Each case history was carefully abstracted either by myself or by my two associates, and it seems desirable to report certain data bearing on the clinical manifestations of ulcer as revealed by this study, as the series constitutes a relatively well studied group, particular care having been given through the years to the writing of complete case histories.

Incidence.—As to sex, 917 (75 per cent) were men and 307 (25 per cent) were women.

Symptomatology.—The average age at the reported onset of symptoms was 35 years, but seemingly no age is exempt, chronic ulcer with marked deformity of the duodenal cap and hemorrhage having been observed in a child of 5 years.

The average time of the first appearance of symptoms before coming under our observation was no less than seven and one-half years. This figure is interesting as indicating the marked degree of chronicity of the ulcers dealt with in this series.

Few chronic ulcers exist without causing some discomfort or pain. Of these 1,224 patients, 49 per cent described their subjective sensation as discomfort or distress and 51 per cent as actual pain. A typical time relationship of pain or distress to food taking is recorded in 1,143 of these histories. The distress appeared from one to three hours after eating in 232, or 20 per cent; from two to three hours after eating in 541, or 48 per cent, and from three to four hours after eating in 370, or 32 per cent.

These figures should set at rest all question as to the consistency of the pain or distress symptom picture produced by peptic ulcer. The pain or distress of uncomplicated ulcer is directly related to the acid content of the stomach. This fact has long been of primary value in the bedside diagnosis of ulcer and has been experimentally verified by Palmer.[3]

* Read before the Section on Practice of Medicine at the Eighty-First Annual Session of the American Medical Association, Detroit, June 27, 1930.

[1] Sippy, B. W.: Gastric and Duodenal Ulcer: Medical Cure by an Efficient Removal of Gastric Juice Corrosion, J. A. M. A. **64**: 1625 (May 15) 1915.

[2] Hurst, A. F.: The Constitutional Factor in Disease, Brit. M. J. **1**: 823 (May 7) 1927. Adler, Erich: The Hereditary Occurrence of Gastric and Duodenal Ulcer, Arch. f. Verdauungskr. **37**: 393, 1926.

A description of the type of discomfort or pain is found in 720 cases.

Where recorded, there was invariable relief by food taking and by the use of adequate amounts of alkaline substances.

Ulcer pain is with few exceptions sharply localized to a definite and small area in the epigastrium. Exceedingly few patients report distress or pain originating below the level of the umbilicus, nor is the radiation of pain very common, as shown by table 2.

Table 1.—*Type of Distress or Pain Described in Seven Hundred and Twenty Cases of Peptic Ulcer*

Gnawing	30 per cent
Burning	30 per cent
Fulness or pressure	16 per cent
Aching	15 per cent
Cramplike, sharp or cutting	8 per cent
Boring	1 per cent

Pain awakening the patient from sleep during the night hours occurred in no less than 425 cases (34 per cent), striking evidence of the great frequency of delayed emptying time and the frequently associated continued gastric juice secretion.

Vomiting.—Spontaneous (not induced) vomiting occurred as part of the clinical picture in 17 per cent of these patients.

Hemorrhage.—Massive hemorrhage occurred prior to admission to the medical services in 19 per cent of cases. Replies to questionnaires show that subsequent to discharge from the medical services hemorrhage occurred in 6 per cent, making an impressive total of 296, or 24 per cent, of these patients who at some time during the course of illness had gross hemorrhage from ulcer.

Perforation.—Perforation occurred at some time during the life history of these patients in 43 cases (4 per cent).

Physical Signs.—Visible gastric peristalsis of pathologic grade was recorded in 185 charts (15 per cent). The records regarding the presence or absence of a circumscribed point of definite local tenderness on palpation are incomplete, but I am increasingly impressed with the significance of this finding as evidence of active ulcer, especially when present in the area most accessible to palpation, namely, the duodenum.

Table 2.—*Radiation of Pain in Peptic Ulcer*

	Number of Cases	Per Cent
To back	78	6.0
To right hypochondrium	7	0.5
To left hypochondrium	6	0.5
To lumbar region	6	0.5
Upward into thorax	4	Less than 0.5
To right lower quadrant	3	Less than 0.5
To left lower quadrant	3	Less than 0.5

Laboratory Observations.—Interesting data are available as to the hydrochloric acid values. The figures presented in table 3 were obtained by routine Ewald test breakfasts and represent the titration figures in terms of tenth-normal sodium hydroxide.

Thus it is seen that less than 3 per cent had an Ewald free hydrochloric acid acidity below 20. In 22 per cent the acid values were between 20 and 40, and 75 per cent of these cases presented acid values above 40, confirming the general impression as to the prevalence of a high acidity in chronic ulcer.

Focal Infection.—Recorded evidence was found in 254 patients, 158 having periapical dental caries, 83 diseased tonsils, and 13 sinus or other infections. A serious effort was constantly made to remove potential sources of general infection.

Roentgen Evidence.—Data are available in 1,036 cases. Roentgen-ray reports are missing from the records in 188 cases because of an imperfect recording mechanism in the earlier years. This group of patients was scrutinized with great care to exclude any doubtful cases. Some positive evidence of ulcer (chiefly history of hemorrhage) was present in 85 of these cases and 17 additional (a total of 102) were proved ulcers at subsequent operation or postmortem. Normal or inconclusive observations were reported in 24 cases.

Duodenal ulcer was diagnosed by roentgen-ray in 923 cases and gastric ulcer in 77 cases, and both gastric and duodenal ulcer in 12 cases.

This relatively low percentage of gastric ulcers is at variance with pathologic reports and I believe is to be explained by a faulty roentgen-ray technic during several of the earlier years covered by this report. This I suspect from the results of the much more precise roentgen-ray methods of recent years. Also, many duodenal ulcers escaped fluoroscopic diagnosis in the earlier years because of inability to visualize the common "fleck" type of lesion on the posterior wall, so often present without recognizable deformity of the silhouette of the duodenal cap.

Table 3.—*Gastric Acidity in 1,224 Cases of Peptic Ulcer*

Number of cases with free hydrochloric acid between:	
1 and 20	33
20 and 30	87
30 and 40	180
40 and 50	238
50 and 60	250
60 and 70	210
70 and 80	120
80 and higher	75
No record	33

RESULTS OF TREATMENT

Preliminary to a discussion of the end-results of treatment, it should again be made clear that this series includes cases in which the patients were admitted to the medical services during the fifteen year period from 1912 to 1927, and no patients entering the hospital later than 1927 have been included, hence a period of not less than two and one-half years has elapsed since treatment of the most recent cases.

In applying the term "cured" to a certain group of cases it must be understood that the word is used to describe the present status of the patient, with complete understanding of the fact that during the next five years probably more than a few individuals in the present cured group will again be suffering from peptic ulcer.

During the past two decades discussion of the treatment of ulcer has too often been chiefly a somewhat acrimonious debate between the physician and the surgeon as to whether ulcer should be considered a medical or a surgical disease. Happily that time is now past and time need no longer be wasted in a futile statistical race, for both the surgeon and the internist have acquired during this period a breadth of experience that has defined with reasonable clarity the manner in which each may with good effect function in securing to the ulcer sufferer health or a measurable degree of relief. There are few indeed who would not now agree that ulcer in its earlier course can be healed by proper medical measures. One cannot escape the thought that, if all patients were really well cared for during the first few weeks or months of the disease, with proper advice as to a subsequent regimen designed to lessen the likelihood of recurrence, the mortality, economic loss and suffering from this malady would be greatly reduced.

---

[3] Palmer, W. L.: The Mechanism of Pain in Gastric and Duodenal Ulcer, Arch. Int. Med. 38: 694 (Dec.) 1926.

One of the most disturbing facts discovered in our survey is that the first manifestations of ulcer so far as could be determined by careful history taking occurred on an average of seven and one-half years before the patient came under our observation. Many of these patients, had they consulted a physician early and had the lesion been accurately diagnosed and well treated at an early stage, would not have developed the sequence of pathologic changes such as scar tissue obstruction and extensive callous formation which later placed so many of them in the category of surgical cases.

Another equally disturbing fact emerges from this record, namely, the large number of cases discharged from our medical services to continue medical treatment under the great handicap of some degree of cicatricial pyloric obstruction (this term being used in the broad sense of obstruction at or near the pylorus). These patients left the hospital with the same complete relief of symptoms as was true in the simple, nonobstructive group, and with the same instructions with the exception of two important additional ones; namely, to empty the stomach with the tube at bedtime and to report in from three to six months' time for determination of the then existing degree of obstruction, with gastro-enterostomy to be advised if the obstructive factor had not then disappeared from the picture.

Table 4.—*Results of Medical Treatment of Peptic Ulcer*

Total number of cases		1,224	
Average duration of symptoms prior to coming under our observation		7½ years	
Number of cases treated wholly medically at the Presbyterian Hospital		1,130	
Number of cases referred from the medical services to surgery		94	
Of the 1,130 cases treated wholly medically, the present status as determined by letters, questionnaires and personal interviews is as follows:			
Good medical result	*Cured*	559 (49 5%)	66%
	Greatly improved	*189 (16.7%)*	
Fair medical result, improved		111 (10%)	
Poor medical result	Not improved	31	*223 (20%)*
	Subsequently operated on for ulcer elsewhere	155	
	Died from ulcer or its effects	37	
Died (*a*) from causes unknown		45	
(*b*) *from causes other than stomach lesions, (chiefly cardiovascular renal)*		54	
(*c*) from carcinoma of stomach		10	
Total		109	

Average present age in this group of 109 cases had patients lived to the present time would have been between 65 and 70 years.

What actually happened in the great proportion of these obstructive cases was this: As time passed, the patient, comfortable, at his usual vocation, eating most foods, and with no trace of dyspepsia, gradually relaxed or abandoned the measures advised (especially the vitally important bedtime aspiration), in too many instances failed to report for reexamination, and several months or years later suffered a recurrence of pain or hemorrhage. Another group included in the total of our poor results is that in which surgery was advised before the patient left the medical service but was refused.

Too much stress cannot be placed on the importance of the bedside recognition of an existing pyloric obstruction. To this end the seven hour motor test meal and cautious inflation of the stomach to render visible the vigorous peristaltic waves of an hypertrophied gastric muscle wall are valued aids. Once recognized as a complicating factor, pyloric obstruction not only immediately demands special medical measures designed to control continued night secretion and insure an empty stomach during the night hours but with equal insistence labels the lesion as potentially a surgical ulcer. In many cases the existing pyloric obstruction is due to muscle spasm and inflammatory swelling, readily relievable by two or three weeks of good medical management. Whatever degree of pyloric obstruction remains after such a brief course of treatment is likely to be due to scar tissue and, if the lumen of the pylorus or duodenum is narrowed by scar tissue to a degree that prevents the stomach from emptying in approximately normal time, the patient should be referred to the surgeon.

It is my belief that the 20 per cent of poor results recorded in this survey represents approximately the proportion of cases of gastric and duodenal ulcer requiring surgical care.

It is interesting to note the evidence indicating the large group of obstructive cases in this series and to contrast these figures with the relatively small number referred by the medical services to surgery between 1912 and 1927. No less than 34 per cent (425 patients) gave a history of pain during the midnight hours. One hundred and eighty-five histories contain a record of visible peristaltic waves. Ninety-four patients were referred to the surgeon. I believe that approximately three times this number of our patients should have had the benefit of skilled surgery. A corollary to this statement, however, is my equally decided opinion that good cooperation between the internist and the surgeon is of utmost value in securing good results. The patients should be placed in the surgical category only after careful clinical study and rarely except after a period of preliminary medical treatment. Gatewood[4] recently reported to the American Surgical Association in Baltimore a mortality of 1.6 per cent in the gastro-enterostomies done at the Presbyterian Hospital over a period of ten years, stressing the important influence of careful preliminary medical treatment prior to and subsequent to operation in obtaining this low mortality rate.

Many authorities still adhere to the belief that gastric ulcers should invariably be excised because of the existing impression that these lesions frequently become cancerous. The series of gastric ulcers in which I was able to secure replies is relatively small, many of my cases in this group having been in the floating population class; but it is of interest to note that 41 per cent of the 77 patients report a definite cure; 20 per cent were greatly improved; 12 per cent report improvement, and 19 per cent were operated on either under my direction or subsequently, and only 9 patients are dead. The cause of death of eight of these patients is known, only one having died from carcinoma of the stomach, and even in this case postmortem examination disclosed the scar of a healed ulcer in a region on the lesser curvature wholly apart from the carcinoma.

Unquestionably, old callous saddle-back ulcers of the lesser curvature are difficult and often impossible to heal. These should be excised when possible. I firmly believe, however, that clinical experience in future years will free gastric ulcer from the malignant suspicion in which it is now held by many medical men and that the mortality figures will show a low incidence of carcinoma in gastric ulcer patients. Certainly we have found most gastric ulcers readily amenable to medical treatment.

---

[4] Gatewood, to be published.

It is known that even under the most favorable conditions the time required for the healing of peptic ulcers varies within wide limits, many healing readily within a few weeks while others with a broad, thickened callous base adherent to the liver or the pancreas and with scant blood supply require several months for complete cicatrization. The general tendency is toward briefer periods of hospitalization for ulcer patients, and one of the great handicaps in directing the after-treatment would seem to be the difficulty in inducing patients to carry on a rigid regimen during months of what to the patient seems an excellent state of health; for so long as he carries out instructions he is, with very few exceptions, perfectly comfortable. In many of the "poor result" cases in this series the replies to questionnaire show that the patient had abandoned all but very sketchy measures of treatment soon after leaving the hospital, content with the temporary benefit secured. To meet this phase of the problem a special outpatient ulcer clinic is being established in charge of an assistant who will endeavor to maintain contact with each patient at stated intervals for at least a year after discharge from the hospital, checking up the details of treatment and the progress of the cases in much the same manner as is done in well organized diabetic clinics. This may be done without cost to the patient and is essentially an educational part of the treatment of ulcer. The tuberculous, the nephritic and the diabetic patients are carefully instructed as to diet, sleep and exercise, as to the use of alcohol and tobacco, and as to the danger of harboring foci of infection. The individual who for years has been the victim of recurrent peptic ulcer would seem to be in equal need of similar personal instruction and supervision.

My purpose in undertaking the survey was to secure information regarding a large group of medically treated cases of gastric and duodenal ulcers covering a long period of years with a view of attempting to crystallize the thought of the profession as to the general effectiveness of the medical treatment of ulcer, treatment of the type based on the conception that an effective control of the free hydrochloric acid in the gastric content is the most important factor in securing healing of peptic ulcer.

CONCLUSION

The present status of 1,224 cases admitted to the medical services of the Presbyterian Hospital between 1912 and 1927 is reported.

Of the 1,130 cases treated medically (94 having been referred to surgery), 49.5 per cent are reported cured, 16.7 per cent satisfactorily improved, a total of 66 per cent of cases in which a good medical result was obtained. An additional 10 per cent report moderate improvement. In 20 per cent, medical measures failed.

Approximately 20 per cent of patients with gastric and duodenal ulcers now being admitted to hospitals require surgical care.

Because of the lack of basic knowledge regarding the etiology of ulcer, the inability of physicians to insure an ulcer-bearing individual against recurrence constitutes the most serious problem to be faced.

310 South Michigan Avenue.

ABSTRACT OF DISCUSSION

Dr. George B. Eusterman, Rochester, Minn.: While some authorities are antagonistic to the neutralization theory and mode of treatment instituted by the late Dr. Sippy, one feels that restoration of normal gastric motility and adequate control of gastric acidity promote healing in suitable cases with the greatest certainty. Such neutralization or adequate reduction by permanent mechanical methods, plus removal of the lesion when feasible, is also the goal of the surgeon. There is ample evidence to show that, in the absence of cicatricial stenosis, adequate control of the morbid secretory state restores normal motor function, and the latter, in turn, exerts a favorable influence on the former. Dr. Brown's report of 49.5 per cent cures, while it may be somewhat of a disappointment to the internist, is commendable. The term "cure" is comprehensive and when such a state is achieved, it in many instances implies not only permanent control of the local factor but certain contributing ones as well, such as unhygienic habits of various kinds, focal infection, the nervous, emotional and physical stress incident to an acquisitive social state, and even the handicap of hereditary or constitutional predisposition. Statistics on cure by purely medical measures, after a five year period of observation, show even a lower percentage according to Nielsen, Crohn, Greenough and Joslin, averaging about 27 per cent. Dr. Brown's more favorable showing can be explained by the more routine intensive and protracted treatment of patients and the fact that a certain percentage of his cases have been observed for less than the five-year period. I have reason to believe that his earlier cases did not have competent roentgenologic verification and observation. The average duration of symptoms in my ulcer-bearing patients is nine and one-half years, and the average age is 45 years. In less than one third of these had a previous diagnosis of ulcer been made, and in only 10 per cent was satisfactory antecedent treatment instituted. I will comment on that group of duodenal ulcer-bearing patients, often with lesions of long standing, who present a persistent mild clinical course without the development of serious complications, and many of whom come under observation for reasons other than digestive disorders. The amenability of these individuals to ambulant treatment, even when not intensive, is shown in the replies to a recent questionnaire or the results of personal reexamination. In 520 of such individuals who have come under my observation from 1915 to 1926, 35 per cent considered themselves cured and 43 per cent as definitely improved and suffered no loss of time from work. In the remainder, death from other causes, persistence of symptoms, acute perforation, severe hemorrhage or necessity for surgical intervention characterized their clinical course. Early gastric and duodenal lesions in young persons usually heal readily under treatment, with good cooperation. Undoubtedly, the ultimate welfare of the patient with an active, long-standing or complicated gastroduodenal ulcer is best conserved by competent surgical intervention.

Dr. H. L. Bockus, Philadelphia: I was pleased to hear Dr. Brown mention the importance of local tenderness in active ulcer. More than half of my cases have tenderness localized to a small area in the epigastrium, which gradually disappears as the ulcer becomes quiescent. It usually survives the subjective pain by several days or weeks. I do not increase the diet as long as tenderness persists. Dr. Brown reports 75 per cent of cases with an acidity above 40. It is well known that the acid values in gastric ulcer are much lower than in duodenal ulcer. In my clinic the acidity, as determined by the fractional method, has recently been reviewed in 200 cases of duodenal ulcer. Fifty-seven per cent had a fasting hyperacidity (hydrochloric acid above 20) and 84 per cent a postprandial hyperchlorhydria (hydrochloric acid above 50). The finding of a subnormal acidity by the fractional method should cause some hesitation in making a diagnosis of duodenal ulcer. Only 8 per cent of the cases were hypo-acid. In seventy-one I checked the acidity at a period varying from six months to six years following the institution of medical treatment. The acidity at the second test was higher in forty-eight, the same in twenty, and reduced in only 32 per cent. Relapses were not more frequent in cases showing extreme hyperacidity at the time of the original examination than in patients with a lesser degree of acidity. However, if reexamination showed a tendency for the acidity to mount even higher, a relapse was often imminent or had actually occurred. I concur with Dr. Brown's opinion that better results would be obtained from medical management if it was instituted more promptly after the onset of symptoms. It has been my policy to advise surgery if after four weeks considerable retention persists, as determined by the fractional analysis or roentgenologic study. Some degree of fibrosis is invariably found in these cases at operation. The necessity for a period of medical management preliminary to surgery, time being allowed for the inflammatory swelling to subside, should be more generally recognized and practiced. It is comforting to hear that not one of the seventy-seven cases of gastric ulcer has become malignant. My experience has been the same. In order to reduce the probability of recurrence in ulcer-bearing patients with seasonal incidence of attacks, I have adopted the following plan: One month previous to the time of expected relapse, the patient's diet is again restricted. He is instructed to take additional rest and to avoid undue fatigue and excesses of all kinds, particularly nervous strain. Restrictions are continued for two months.

Dr. G. Gill Richards, Salt Lake City: In 1917, a summary of 100 cases of peptic ulcer at the Salt Lake Clinic revealed that 75 per cent of them had been treated by surgery. As our experience grew the number of cases referred for surgery lessened. By 1926, only 30 per cent of the patients were operated on. From 1926 to 1930 only 12 per cent of 278 patients with duodenal ulcers were referred for surgery. It is the other group of peptic ulcers in which I have been especially interested the last four years. Up to 1926 my associates and myself had been so thoroughly converted to the teaching of the frequency of development of a malignant condition on gastric ulcers that it was our custom to recommend surgery in all cases of gastric ulcer. Early in 1926 I became so upset at the loss of two of these patients from postoperative pneumonia that I began to fear pneumonia more than carcinoma. With the greatest of care we selected a small group for medical probation. We insisted on a reexamination every two weeks at the beginning, and every two months during the first year. To our amazement, the small ulcer niche had disappeared and the larger ones were much smaller, even at the end of the second or third week. Of the forty-eight patients with gastric ulcer whom we have had in the last four years only fifteen have been operated on. A failure to obtain complete healing or a return of the ulcer while on careful diet seems sufficient to recommend surgery. In this group recurrence has been less frequent than in any similar series of duodenal ulcer, and the ulcer heals with no visible deformity. Up to the present time none have developed any symptoms or signs which lead us to suspect a malignant condition, and only one of those treated medically has died from the ulcer. At autopsy there was no sign found of any malignant growth.

Dr. Ralph C. Brown, Chicago: The chief purpose I had in mind in making this survey was to ascertain the precise facts regarding the fate of ulcer patients, having in mind the statement made by Dr. Sippy that 85 per cent of them could be cured, as well as his strong feeling against the ill considered and indiscriminate reference of cases to surgery. I was also anxious to attempt by means of these statistics to influence the thought of the profession as to the general effectiveness of the type of medical treatment which is based on the conception that an effective control of free hydrochloric acid in the gastric content is the most important factor, although by no means the only factor, in securing healing of peptic ulcer. I have learned that this type of medical management is based on a valid principle. Curiously enough, this knowledge has come not alone from observation of the cases that could readily be cured by Sippy treatment but possibly even more definitely from experience with cases that could not be cured medically, nearly always cases in which for one reason or another it was not possible to achieve complete neutralization of free hydrochloric acid. This recalls the case Dr. Eusterman cited of the patient who recovered without alkalis on a diet limited to bread and milk. There are patients who will not do well on Sippy treatment in the sense that they are unable to tolerate the intensive use of various alkalis, and it may be of interest to know that ulcers are being cured without alkalis in certain individuals of this type by giving milk and cream at very frequent intervals, using milk as a neutralizing agent. It is known that milk will neutralize the free hydrochloric acid in approximately an equal volume of gastric juice. There are certain other cases (not common) in which there is stimulation of a continued night secretion by the administration of alkalis. In such susceptible individuals it is impossible to heal a very large lesser curvature gastric ulcer by routine measures of medical management and I have recourse either to a prolonged course of duodenal tube feeding or, still better, to the use of two small tubes, one in the duodenum for feeding and the other in the stomach. By means of this shorter tube the stomach may be kept free from accumulation of acid gastric juice by very frequent aspirations. I know of few conditions in medicine offering as much opportunity for individualization in treatment as is possible in the application of the Sippy principle to the treatment of peptic ulcer, with all the idiosyncrasies which various ulcer patients exhibit.

MENSTRUAL DISORDERS IN ADOLESCENT GIRLS

THEIR SIGNIFICANCE AND TREATMENT *

CHARLES H. LAWRENCE, Jr., M.D.
BOSTON

A study of sterility now in progress at the Evans Memorial[1] shows that, in fifty consecutive cases, 54 per cent of the women had definite pelvic hypoplasia as one of the more important factors in the sterility. Of these, 66 per cent gave convincing evidence of endocrinopathy still existing, and an additional 14 per cent gave histories which were strongly suggestive of adolescent disturbances of endocrine function which had spontaneously normalized in early adult life, leaving as residua various degrees of permanent incomplete development of the reproductive organs.

Because of this large incidence of pelvic hypoplasia in sterile women, and its incurability when detected after the growth period is over, it seemed worth while to study adolescent girls with symptoms suggestive of imperfect development of the reproductive organs, in order to determine the cause, the nature and, if possible, the effective treatment of that condition, so that it might be applied before normal development became an impossibility.

To this end, 100 women with delayed menarche or delayed or scanty periods were studied to determine the presence or absence of pelvic hypoplasia and the systemic disturbances associated with it. Fifty of the patients were sterile married women and fifty were adolescent girls. In the former, the presence of ill developed reproductive organs was determined by vaginal pelvic examination and its extent at least approximately measured by calculating the uterine index by Meaker's[2] method. In the latter group, vaginal examination and determination of uterine index were not often practicable, and the condition of the pelvic organs was ascertained by rectal examination. Although this gives less certain results it is sufficient to rule out pathologic conditions of the pelvis, and the degree of hypoplasia is of less importance in the

adolescent group since the chance of normal growth still exists. The age of onset and the character of the menstrual flow could be obtained with equal accuracy in the two groups. Rubin[3] has shown, in a recent study of sterile women, that women who menstruate normally have at least a twelve times better chance of pregnancy than those whose menses are habitually delayed or scanty. These criteria, therefore, were selected for examination in this study.

There is still lack of complete agreement concerning the latter limit of normal menarche, but the consensus seems to place it during the fourteenth year. Engleman[4] analyzed more than 10,000 case histories in the United States and Canada and found the average age of the menarche to be 13.9 years. An analysis of 500 apparently normal women at the Evans Memorial shows that about 80 per cent have begun to menstruate before their fourteenth birthdays. One half in the series have borne children; one half were unmarried. For the purpose of this paper, therefore, the fourteenth birthday was selected as marking the latter limit of strictly normal menarche, although from a practical point of view its delay for another twelve months cannot be said to be proof of significant retardation.

The normal interval between menstrual periods is generally regarded as twenty-eight days and was so accepted in this analysis, though a few days' variation, unaccompanied by other abnormal characteristics, was not interpreted as abnormal.

The duration of the normal menstrual flow was set at from four to six days in this study, though Novak[5] sets the limits at from three to five days, and other authors do not regard seven days as unduly long. Variations of a day or two were not interpreted as abnormal in the series here reported.

† Of thirty-four examined by rectum.

In deciding whether or not the amount of flow was normal in any patient, her own statement was accepted for want of a better criterion, and the amount is described as normal, profuse or scanty according to the patient's statement.

The diagnosis of the endocrine disorders associated with the menstrual disturbances was made on the history and physical examination supplemented by a metabolic study including the usual laboratory examinations. The necessity for so complete a study in differentiating endocrine disorders from one another and from nonendocrine conditions simulating them has been so emphasized elsewhere by Rowe and myself[6] that comment on the tests selected is unnecessary here.

The results of the study are reported in table 1. The observations are significant for two reasons. First, they show a high incidence of disturbed endocrine function associated with pelvic hypoplasia, delayed menarche, oligomenorrhea and hypomenorrhea. Second, the association is significantly similar in the adult and in the adolescent group, the differences probably being due to the fact that a certain number of adolescent endocrine disturbances have spontaneously and entirely disappeared by the time the age of marriage is reached. A comparison of the figures, however, indicates that the odds are strongly against such an outcome, and that the adolescent girl with delayed menarche and with infrequent, irregular or scanty periods is likely to be of low fertility when growth has ceased, since the pelvic hypoplasia will then be permanent, whether the associated endocrine disturbance persists or not. The chance of cure lies in identifying and removing or compensating for the underlying cause while growth and developing are still possible.

In the past, attempts have been made to meet this need by administering some one of the various ovarian extracts that are available. With rare exceptions, the results of such treatment have been nil, and the blame for failure has by unanimous consent been laid on the quality of the extract administered rather than on the impropriety of administering ovarian extract at all.

An analysis of the results in this study, together with other recent evidence, offers another explanation for the failure of ovarian extract to be effective in delayed menarche or oligomenorrhea. Table 2 gives the distribution of the systemic disturbances associated with those symptoms in the group studied. From it, it appears that the largest single factor found associated with disturbed menstrual cycles was insufficiency of pituitary function, and that primary insufficiency of the ovarian hormones not due to ablation of or pathologic changes in the glands is a comparatively rare condition.

Such a conclusion constitutes a radical departure from generally accepted theory. It has, however, the support of the more recent knowledge concerning the rôles played by the ovary and pituitary in the control of menstruation, ovulation and pregnancy.[7] These newer ideas have been recently reviewed by Novak[5] and by Johnstone.[7] Novak says: "The most important recent contribution to sex physiology, and the one which promises most in its future practical applications, is the discovery that the anterior pituitary constitutes the 'motor' of the ovary."

In the light of this and similar statements and of the almost complete clinical failure of even the follicular hormone to correct disturbances of the menstrual cycle, the observations here presented assume a logical relation to clinical experience. They explain the failure of ovarian extracts and indicate that we should abandon both the attitude of optimistic expectancy concerning delayed menarche and oligomenorrhea in the adolescent girl, and the routine use of ovarian extracts in their treatment. They suggest, for the material is too scanty to do more than that, that disturbed pituitary function is the most common single cause of those symptoms, and they should make it clear that the diversity of possible causes necessitates an adequate study of the patient before any treatment is inaugurated. Not all patients with abnormal menstrual cycles have disturbed endocrine function, even though their basal metabolic rates are below normal. An inadequate nitrogen intake, not uncommon in these days of protephobia, will reduce the basal metabolic level to abnormally low values. A single basal metabolism estimation, even when it yields abnormally low results, is not adequate evidence of the existence of thyroid failure or, indeed, of any other endocrine inadequacy. The differential diagnosis of the systemic disturbance can be reached only by a group of tests which give different results according to the situation existing. In the series here reported, for example, basal rates between minus 10 per cent and minus 20 per cent were found in thyroid insufficiency, pituitary insufficiency, ovarian insufficiency, and in patients with negative nitrogen balance, and the identification of the focus at fault could be reached only by interpreting the metabolic rate in the light of all the other observations. This method gives patterns that we have found characteristic in more than 5,000 patients studied at the Evans Memorial.[6]

TABLE 3.—*Endocrine and Nonendocrine Conditions Affecting Abnormal Menstrual Cycles*

	Fifty Sterile Adults, per Cent	Fifty Adolescents with Abnormal Menstrual Cycles, per Cent
Thyrotoxicosis	2	2

Chronic tonsillar and sinus infection	2	0
Chronic tonsillar and dental infection	2	0
Hepatic toxemia	4	0
Nontuberculous pulmonary infection	0	2
Negative nitrogen balance	18	2

The question may be raised, if we are to insist on such thorough study as a prerequisite for treatment, whether there is available any therapy that will give results justifying the labor and expense involved. The general attitude among clinicians is that with the exception of thyroid extract the various endocrine extracts are inert if given by mouth. The basis for this point of view is the fact that, as usually given, they do not produce satisfactory results. There are a number of possible errors in this reasoning. Our failures may be due equally to our inability to diagnose correctly the endocrine disturbance in the individual patient, to inadequate dosage, to the presence of unrecognized focal infection, and, in adults, to the fact that growth and development are no longer possible. This last factor deserves especial consideration in view of the known effect of the anterior pituitary secretions.

Indeed, the results obtained in the adolescent group of this series suggests that the latter factor is an *extremely important one, for the results obtained* were surprisingly encouraging. The series is too small to prove anything, and the possibility that results credited to treatment may have been due to spontaneous normalization of the disturbed function always exists to plague us. But in comparing the results in the pituitary group with those obtained with thyroid extract in thyroid insufficiency, the difference in successes is not convincingly different (table 4). The criterion of success was the apparent response of the menstrual periods, and only those patients in whom essentially normal menstrual rhythm appeared and persisted for six months or longer are classified as normalized. Those in whom the periods became less infrequent but not monthly and those who have apparently normalized but have been under observation less than six months are classified only as improved, while those who for a period of more than six months have not established normal rhythm are classified as unimproved. From the figures as tabulated, it appears that anterior lobe extract given in adequate dosage by mouth to suitable adolescent patients is nearly as effective as thyroid extract and much more effective than ovarian extract. This is in accordance with the newer knowledge of the physiology of menstruation. It should be added, however, that adequate dosage was found to be from 20 to 60 grains (2 to 4 Gm.) daily in the patients in this series, and that in every patient treatment was preceded by clinical and metabolic studies designed to identify the disturbance of endocrine function present. The comparative effects of anterior pituitary and thyroid extracts in individual patients is shown in table 4. The results suggest that the anterior pituitary hormone which acts as the "motor" of the ovary may be efficient when given by mouth even though there is no demonstrable effect on skeletal growth.

TABLE 4.—*Results of Treatment*

	Menstrual Cycle		
Condition Treated	Normalized, per Cent	Improved, per Cent	Not Improved, per Cent
Thyrotoxicosis	50	25	25
Thyroid insufficiency	80	20	0
Pituitary insufficiency (anterior lobe —, posterior lobe +)	66	9	25
Pituitary insufficiency (bilobar)	50	25	25
Ovarian insufficiency (primary)	33	30	36
Nonendocrine conditions	66	19	15

CONCLUSIONS

1. The occurrence of delayed menarche or abnormal menstrual rhythm or flow in adolescent females is indicative of subnormal development of the reproductive organs which is likely to result in diminished fertility during adult life.

2. It is more often due to systemic functional disturbances than to pelvic disease, and of those disturbances insufficiency of the anterior pituitary hormone is the commonest.

3. Spontaneous compensation of such conditions does occur, and treatment is not indicated by slight delay in establishing normal menstruation; but, if that function has not become normal by the sixteenth year, the attitude of optimistic expectancy must be abandoned.

4. In the great majority of these adolescent patients, the symptoms are not due to primary ovarian insufficiency but to some endocrine or nonendocrine systemic condition that renders the potentially normal ovary inert. The commonest of these conditions are focal infection, insufficient protein in the diet, and insufficiency of the anterior pituitary hormone.

5. In the series here reported, the oral administration of anterior lobe pituitary substance, in adequate dosage, has given encouraging results in patients in whom the existence of such a pituitary insufficiency was demonstrated.

520 Commonwealth Avenue.

ABSTRACT OF DISCUSSION

DR. C. J. MARINUS, Detroit: Dr. Lawrence's demonstration that in 50 per cent of his cases of sterility in adults there was a hypoplasia of the pelvic organs is a fact which, if accepted at all, must be given a great deal of importance. The reason for the presence of this hypoplasia should be found. His further demonstration that in the presence of a pelvic hypoplasia there is a high percentage of pituitary and thyroid insufficiency as demonstrated by careful laboratory and physical examinations is a fact of great significance. As Dr. Lawrence has pointed out, the usual method of handling these patients has been the administration of some form of ovarian therapy. In the beginning, the most common treatment was the use of corpus luteum by mouth. Then whole ovarian substance by mouth and hypodermically was used. With the discovery and preparation of the concentrated follicular hormones, these were used. It has been felt that the use of the follicular hormone was definitely indicated in all cases of amenorrhea, delayed menstruation or scanty menstruation. Indeed, from the practical clinical standpoint there were frequently successful results from the use of this treatment. I have been disappointed in finding, however, that shortly after the treatment was discontinued the menstrual disturbance returned to its previous condition. In other words, the treatment had acted as a temporary stimulant to the menstrual function and had actually accomplished nothing in curing the cause of the condition. Dr. Lawrence's figures have given the true explanation for this real failure in successful treatment. The condition is usually due to a disturbance in one of the other glands of internal secretion with a secondary effect on the ovary. Obviously, treatment with ovarian substances regardless of how potent they may be cannot be expected to give a real cure of the condition. It is hoped that this effort will be a stimulus to more accurate diagnosis in the cases of menstrual disturbances, particularly in the younger individuals in whom treatment can be expected to result in a permanent change for the better.

DR. CHARLES MAZER, Philadelphia: I heartily endorse Dr. Lawrence's classification of the etiology of female sterility but beg to differ somewhat with him as to therapy. I have tried out a large number of preparations produced by reputable firms in this country and in no case have I found, by means of the Aschheim-Zondek test for anterior pituitary hormone, a preparation that yielded a mouse unit of this hormone. Clinically, I have used anterior pituitary extracts by mouth and needle with meager results. In a few patients, improvement was noted. A potent product of the anterior pituitary gland is as yet not obtainable in this country. The Germans claim to have produced a potent product from the urine of pregnant women.

DR. CHARLES H. LAWRENCE, JR., Boston: It is possible that many of these patients spontaneously become normal while they are taking pituitary extract by mouth. Until a large series of cases has been observed it will be impossible to determine how much must be written off for the natural tendency of these things to become normal. Until some method of physiologically standardizing endocrine products has been evolved, I don't know how any other test than clinical experience can be used. There is neither time nor space to illustrate some of the cases on which this paper is based but it seems to me that, if medication is pushed to a sufficient dosage, if foci of infection are removed, and if the patient's general condition is improved, surprisingly good results may be obtained in the pituitary group. Certainly, it seems to me far preferable than the administration of ovarian therapy.

THE SIGNIFICANCE OF ADVANCED TUBERCULOUS INFECTION OF SCHOOL CHILDREN [*]

EUGENE L. OPIE, M.D.
PHILADELPHIA

Within the last five years, extensive studies by Opie and McPhedran,[1] Chadwick,[2] Rathbun,[3] Myers,[4] and Opie, Landis, McPhedran and Hetherington [5] have demonstrated the widespread occurrence of grave tuberculous lesions in the lungs of children who do not seem to be sick and in many instances are well nourished and apparently in robust health. These children do not have the symptoms or physical signs usually associated with pulmonary tuberculosis. Tuberculous infection is discovered by the tuberculin test, and roentgenologic examination furnishes a measure of its severity by revealing the extent and character of the lesion. Within a short period a considerable amount of information has been accumulated concerning the clinical significance and probable outcome of the different lesions that are definable, but as yet this knowledge is incomplete and will be increased largely by observations continued for years, because the disease usually pursues a chronic course. Knowledge of the prolonged latent period of tuberculosis is gradually being enlarged.

These studies have shown that the transition from latent to clinically manifest disease is often defined with much difficulty and that some latent lesions are more extensive than those that are accompanied by symptoms and physical signs.

Studies undertaken with the aid of all available methods to discover tuberculosis in school children have shown, moreover, that a considerable number of children who suffer with clinically manifest tuberculosis escape the attention of parents, teachers, school nurses and physicians, even though medical inspection is as effective as possible. In association with advanced infiltration of the lung substance recognized by roentgenologic examination either at the apex or, less frequently, in other parts of the lung field, there may be deficient expansion, diminished resonance and râles. In a relatively small number of instances, inquiry discloses persistent cough. In such cases a history of contact with tuberculosis has seldom been obtained from the children directly, but the parents more frequently reveal the child's association with some one who has apparently suffered with the disease.

A survey [5] undertaken by the Henry Phipps Institute to discover tuberculosis in children of the public schools has been conducted with the aid of a grant from the Metropolitan Life Insurance Company. It has had the cooperation of the Division of Medical Inspection of Schools under the direction of Dr. Cornell. In most of the schools that were investigated, pupils were tested with tuberculin and those who reacted were given roentgen examination and when necessary physical examination.

Table 1 is compiled from the data collected by the survey of school children in Philadelphia made by Opie, Landis, McPhedran and Hetherington to show the incidence of grave tuberculous infection at different ages.

Table 1.—*Tuberculous Infection in Children Attending School*

Years	Children Tested with Tuberculin	Children That Reacted	Children That Received Roentgen Examination	Tuberculous Foci in Lungs or Lymph Nodes, per Cent	Childhood Type of Tuberculosis: Latent Infiltration, per Cent	Childhood Type of Tuberculosis: Clinically Manifest, per Cent	Adult Type of Tuberculosis: Latent Apical, per Cent	Adult Type of Tuberculosis: Clinically Manifest, per Cent
5-9	572	284	124	5.9	1.2	0.6	0	0
10-14	683	467	452	13.9	2.1	0.5	0.5	0.1
15-19	1,295	1,066	1,060	20.1	1.9	0.2	1.0	0.5

Tables 20 A and 20 B of the report [5] should be consulted. The first school examined has been eliminated from the enumeration because only a small part of the children who reacted to tuberculin received roentgenologic examination. Children between the ages of 5 and 9 years included in the table were given roentgenologic examination if they reacted to 0.01 mg. of tuberculin. Table 23 of the report shows that the percentage of grave lesions (latent infiltration of childhood type, latent apical lesions and manifest tuberculosis) will not be materially altered by excluding children who reacted to smaller quantities of tuberculin.

CALCIFIED NODULES IN THE SUBSTANCE OF THE LUNG

Minor tuberculous lesions of the lung substance are not recorded on roentgenograms because small foci of consolidated lung tissue, even when they have undergone caseation, are not sufficiently opaque to x-rays. When calcium is deposited in caseous tissue very small lesions become conspicuous, even though the amount of calcium present is not enough to change materially the consistency of the caseous material. There is abundant evidence that tuberculous lesions of the lung may resolve completely or in part, but dissolution of lesions is certainly retarded, if not wholly prevented, by caseation. Tuberculous foci that have undergone calcification persist throughout life as scars readily recognizable in roentgenograms unless they are concealed by opaque organs.

TUBERCULOSIS OF TRACHEOBRONCHIAL LYMPH NODES

Tuberculosis of the tracheobronchial lymph nodes is evident in roentgenograms when caseous material has become partially or completely calcified. Caseous lymph nodes with no calcification are recorded in roentgenograms only when they have undergone massive enlargement. The lymph nodes that are the sites of visible tuberculosis are found at the hilus of the lung in contact with the larger bronchial trunks, below the bifurcation of the trachea, where the largest lesions are found, and on one or the other side of the trachea, being usually more conspicuous on the right. Masses

† C indicates colored; W, white.

below the bifurcation of the trachea are occasionally from 2 to 5 cm. in diameter. Dense, sharply defined opacity suggests that calcification is advanced, whereas shadows of less density occurring in small spots, which give a granular appearance to the lesion, suggest the early stage of calcification.

The associated pulmonary lesion is often invisible, being small or behind an opaque organ; but in more than half of the instances in which tuberculosis of tracheobronchial lymph nodes is evident a calcified nodule or, less frequently, the shadow of diffuse infiltration is seen in the lung field nearby. Almost always these lesions are smaller or less conspicuous than those of the tracheobronchial lymph nodes, and for this reason are less frequently recorded in the roentgenogram.

Calcium deposited in caseous material casts a conspicuous shadow on the film even though the caseous material, as can be shown at autopsy, is putty-like and contains no solid particles. Calcification recognizable in roentgenograms does not prove that the lesion is arrested, for observations made post mortem have repeatedly shown that the disease may be progressive in the lung even though the lymph node is the site of calcium deposit, and that tuberculosis of lymph nodes may be progressive even though foci of calcification occur within them.

TABLE 3.—*Tuberculosis of Childhood Type with Symptoms or Physical Signs (Clinically Manifest)*

Designation of Child	Sex	Age	Race	Per Cent of Normal Weight	Reaction to 0.01 Mg. Tuberculin	Temperature	Site of Associated Tuberculous Lesion	Symptoms	Physical Signs	Comment

MASSIVE TUBERCULOSIS OF LYMPH NODES WITH NO CALCIFICATION

Increased density of ill defined hilus shadows or recognition of a thickened mediastinal shadow does not identify tuberculosis of tracheobronchial lymph nodes. Tuberculosis of the mediastinum, which has been admirably described by Kornblum and Cooper,[6] probably does not occur in children able to attend school.

Small caseous lymph nodes are not recognizable in roentgenograms of the chest, but massive tuberculosis of these organs may cause such enlargement and opacity that their rounded outline is distinctly recognizable. The shadow of the structures at the hilus tends to obscure them, but when they project into the clearer lung field their outline becomes visible.[7] Similarly, lymph nodes beside the trachea can be traced when they project far enough beyond the usual lateral margin of the mediastinum.

In a girl aged 10 years, the oval outlines of two large uncalcified lymph nodes were recognized in the right hilus and a third at the right side of the trachea. One year and three months later, calcification in small spots could be seen. In a second child, aged 10 years, a dense oval shadow, 3.5 by 1.5 cm., was situated at the right of the trachea and projected into the lung field. In a boy, aged 7 years, an immense rounded mass, 6.4 by 3.5 cm., was outlined at the right hilus and beside the trachea; infiltration of the lung substance extended from it to the periphery of the lung. Three months later physical signs of tuberculosis (râles) were recognized and pulmonary infiltration had increased, but the mass was no longer defined with certainty.

This lesion may heal completely and produce the massive calcification of tracheobronchial lymph nodes occasionally seen in adolescent children and adults. Nevertheless it has obviously grave significance and has been the precursor of acute miliary tuberculosis.

TUBERCULOUS INFILTRATION OF THE LUNG OF CHILDHOOD TYPE

In table 2 are collected instances in which infiltration of the lung of childhood type was not associated with symptoms or physical signs. The extent of the infiltration in these children was occasionally as great as in those with symptoms or physical signs cited in table 3 and, save in children older than 14 years, exhibited the same relation to weight and tuberculin reaction. Slight elevation of temperature was repeatedly found in these children, but this occurs so frequently in young children that it could not be referred to tuberculous infection with certainty. In almost all those over 14 years of age the character of the lesion suggested arrest.

In table 3 are collected instances of clinically manifest pulmonary tuberculosis of childhood type. In half of them the weight of the child was above normal for the age and height, and in only one instance was the weight notably decreased. There was elevation of temperature, usually slight, in approximately half of the cases. In all of them 0.01 mg. of tuberculin caused a reaction, which in the majority was intense (++ or +++); cough was present in some. Râles were detected in all save two of these children. In a girl (G 2), aged 19 years, a circumscribed lesion in contact with the diaphragmatic pleura was manifested by deficient expansion, but the character of the lesion and the absence of other physical signs or symptoms suggested arrest of the disease.

[6] Kornblum, Karl; and Cooper, D. A.: Am J. Roentgenol. 23:276 (March) 1930.

[7] McPhedran (footnote 5, fourth reference).

In roentgenograms, tuberculous infiltration of childhood type presumably caused by tuberculous bronchopneumonia with subsequent tubercle formation is usually recognized as a soft, ill defined, occasionally flocculent opacity in any part of the lung field. It is sharply limited only when it comes in contact with an interlobar surface. Calcification of the nearest lymph nodes at the hilus of the lung is not infrequently recognizable and confirms the diagnosis of tuberculosis.

Dense opacity indicates that pneumonic consolidation, presumably with some caseation, has affected a wide area of lung substance. The center of the abnormal shadow is a dense homogeneous opacity, which decreases at the margin, becomes more or less irregular and disappears into the normal lung field. McPhedran[5] has found that such a consolidated area in some instances may undergo resolution, gradually becoming less opaque, particularly at the lateral aspect, and may finally be reduced to strands and spots partly calcified.

Table 4.—*Tuberculosis of Adult Type with no Symptoms or Physical Signs (Latent Apical Tuberculosis)*

G 7	♀	White	17	90	+	98.2	

In older children, usually after 14 years of age, recognizable tuberculous lesions in the lung fields are usually strandlike and contain calcified nodules. Even though there is an active tuberculin reaction, such lesions are doubtless in most instances arrested.

In twenty-five among forty-five instances of the childhood type of pulmonary tuberculosis, both latent and manifest, tuberculosis of tracheobronchial lymph nodes was sufficiently conspicuous to be recognizable in roentgenograms.

LOCALIZED TUBERCULOSIS OF PLEURA AND UNDERLYING LUNG

In two instances (D 7, table 2 and G 2, table 3) roentgenograms have clearly defined tuberculous masses situated in contact with the pleura and evidently invading a narrow zone of lung tissue. In one instance the lesion extended from the seventh to the tenth rib in the axillary line and in the other it covered the diaphragm from the left border of the heart to the costophrenic angle. The pulmonary aspect of the mass was sharply defined and rounded. I have seen this lesion twice in adult Negroes, in one case associated with massive caseous tuberculosis of the nearest lymph node and general miliary tuberculosis.[8]

PULMONARY TUBERCULOSIS OF ADULT TYPE

Table 4 contains instances of latent apical tuberculosis, in some of which the lesions are as advanced as those accompanied by symptoms (table 5). In approximately one third of those with latent lesions there was overweight and in an equal number there was notable underweight. The tuberculin reaction was, as a rule, less intense than with clinically manifest apical disease, and the temperature was seldom elevated.

Apical lesions when least conspicuous appear as soft shadows or mottling below the border of the second rib. Wedges or salients projecting downward in this position are not infrequently seen. The extent and density of the infiltration varies widely. The lesion may occupy the entire apex above the clavicle, and, even though unaccompanied by symptoms or physical signs, may extend below the clavicle in the axillary region.

Sharply defined strandlike shadows in the apex suggest that the lesion is in the process of healing, but this evidence is uncertain and repeated examinations are essential to exclude the possibility that the lesion is progressive.

Table 5 contains instances of the adult type of pulmonary tuberculosis recognized in school children by roentgenologic examination and by physical signs. Weight is more frequently diminished than with the childhood type of infection; it is in none of these cases above normal and in several there is noteworthy underweight. There may be scant increase of temperature. Râles were less frequently heard than with the childhood type of pulmonary tuberculosis.

Among thirty-one instances of pulmonary tuberculosis of adult type, clinically manifest and latent, tuberculosis of the tracheobronchial lymph nodes was recognized in thirteen, and in nearly all of these a calcified nodule was found in the lung field nearby.

VALUE OF THE TUBERCULIN TEST

In children able to attend school, failure to react to tuberculin indicates the absence of infection with tuberculosis and demonstrates that a suspected lesion is not the result of this disease.

Exceptions to the foregoing statement are a small number of calcified scars of healed tuberculosis with no reaction to tuberculin. Animal experiments and some clinical observations show that sensitization to tuberculin may disappear after complete recovery from tuberculosis. A few school children with calcified nodules in the lungs and adjacent lymph nodes have failed to react. These children, in whom the lesion is completely healed, have perhaps lost all acquired immunity.

The intensity of the tuberculin reaction has considerable significance. All instances of clinically manifest tuberculosis among school children occurred in those who reacted to 0.01 mg. of tuberculin, and in two thirds of these the reaction was three plus. With few exceptions, children with latent infiltration of childhood type reacted to the same amount, and in considerably more than half of them the reaction was three plus. Three fourths of the children with latent apical tuberculosis reacted to 0.01 mg. of tuberculin.

---

[8] Opie, E. L.: Am. Rev. Tuberc. **10:** 265 (Nov.) 1924.

An intense tuberculin reaction may be associated with an apparently insignificant lesion, but the probability of grave infection increases with the intensity of the reaction.

RELATION OF UNDERWEIGHT TO TUBERCULOUS INFECTION

The traditional association of tuberculosis with loss of body weight has suggested that this symptom may be used for the discovery of concealed tuberculous infection. Hetherington,[9] however, has compared the relation of weight to tuberculous infection in 2,000 school children and his observations show that loss of weight cannot be used as an index of tuberculous infection until the disease is so far advanced that it has undermined health.

Weight below normal is not found more frequently in children who react to tuberculin than in those who give no skin reaction.

HISTORY OF CONTACT WITH TUBERCULOSIS

It is seldom possible to obtain from school children a history of contact with tuberculosis; but, when advanced infection is recognized in a child, consultation with the parents may disclose the source of contagion.

Study of the contagion of tuberculosis in families made during the last six years, and still in progress, at the Henry Phipps Institute has shown that a large percentage of all instances of advanced tuberculous infection occurs in persons known to have been exposed to open tuberculosis within the family group. In these families at least 9 per cent of the children develop clinically manifest disease; many develop latent infiltrating lesions of childhood or lesions of adult type, and tuberculosis of tracheobronchial lymph nodes is found in approximately one fourth of them. The transition from grave latent lesions to clinically manifest disease has been repeatedly followed.

Table 5.—*Tuberculosis of Adult Type*

Designation of Child	Sex	Age	Race	Per Cent of Normal Weight	Reaction to 0.01 Mg. Tuberculin	Temperature	Site of Associated Tuberculous Lesion	Symptoms	Physical Signs	Comment

F 8	♀	18	White	90	+	98.8	....	....	Diminished resonance, deficient expansion	

Many children with recognizable tracheobronchial tuberculosis are considerably above normal weight, and no material loss of weight accompanied this lesion. In three instances of massive caseous tuberculosis of tracheobronchial lymph nodes the body weight has been 90, 92 and 96 per cent of normal.

Among forty-four school children with the childhood type of pulmonary tuberculosis (tables 2 and 3), both clinically manifest and latent, overweight was just as frequent as underweight and when, in only four instances, noteworthy underweight occurred, it was probably not referable to tuberculosis.

Among twenty school children with the adult type of tuberculosis (tables 4 and 5), both the clinically manifest and latent apical, the weight was slightly below normal in fifteen and materially diminished (more than 10 per cent of normal) in five. This lesion evidently may cause some impairment of nutrition in children still able to attend school.

If all school children known to have been exposed to open tuberculosis received tuberculin tests and adequate roentgenologic examination, a large number of those with advanced tuberculous infection would be discovered. Since tuberculosis is a reportable disease there is at hand a means for the selection of children with advanced tuberculous infection.

Children who at the time of examination are still exposed to open tuberculosis are in obvious danger of reinfection, and study of such children shows clearly that in them existing infection provides an inefficient immunization against grave disease. The danger to which children are exposed differs widely in different households; it varies with the character of the lesion in the person who has open tuberculosis, with the habits and cleanliness of the patient and of the family, with the degree of crowding of the household and other conditions. Advanced tuberculous infection, for example, massive tuberculosis of tracheobronchial lymph nodes, indicates that the child has received tubercle bacilli in large number. If this exposure continues, reinfection may result and the adult type of pulmonary tuberculosis makes its appearance; tables 4 and 5 show that apical lesions frequently accompany the calcified scars of a first infection in lung and lymph nodes.

---

[9] Hetherington, H. W.: Am. Rev. Tuberc. **16**: 459 (Oct.) 1927.

Children who have been exposed to open tuberculosis should receive tuberculin tests repeated every year or, if still exposed, every six months, and a child who reacts to tuberculin should be given roentgenographic examination.

WIDESPREAD TUBERCULOUS INFECTION

Intracutaneous tuberculin tests made on 4,000 school children from 1926 to 1929 in Philadelphia show that 37 per cent of the children are infected at 5 years of age, 71 per cent at 10 years, 80 per cent at 15 years, and 90 per cent at 18 years. These figures are only slightly lower than those obtained twenty years ago in Vienna by Hamburger and Monti,[10] who used the same method.

When tuberculin is applied to the scarified skin by the method of Pirquet, much smaller figures have been obtained.

Aronson, at the Henry Phipps Institute, has recently compared the two methods and has found that approximately 25 per cent more school children react to the intracutaneous than to the Pirquet test. Debré and Cofino,[11] applying these tests to infants treated with B C G, found that the number of those who react is increased 75 per cent by the intracutaneous method. It is my belief that the Pirquet test should be discarded as a means of determining the incidence of tuberculous infection. Furthermore, the strength of tuberculin varies widely and must be determined before it is used.

In rural districts tuberculous infection is less widely disseminated than in the cities. Intracutaneous tests made by Slater [12] in Minnesota and a survey of school children in Ontario [13] have shown that the number who react is much smaller in country districts than in the larger cities.

It has been assumed that a fall in the death rate from tuberculosis in cities such as Philadelphia would be accompanied by a corresponding diminution in the number of those who acquire minor tuberculous infection. Nevertheless, observations made on young adults attending college in this city show that at least 95 per cent react to tuberculin. Dissemination of tubercle bacilli is evidently still sufficiently widespread in cities to bring about infection of a large percentage of all children before they reach adult life. Observations at the Henry Phipps Institute show that the relatively small number of these infections acquired at home from a member of the family suffering with open tuberculosis are far more severe than those acquired by casual contacts outside the household. With the falling death rate from tuberculosis during recent years there has been diminution in the severity of infections, but in the cities at least no notable diminution in their number.

Furthermore, since the incidence of infection increases rapidly from infancy to the tenth year, when 70 per cent of children are infected, it may be assumed that opportunity for similar infection is repeated throughout life, probably with increasing frequency. From experiments on animals and observations on human beings it is known that sensitization to tuberculin disappears when the tuberculous lesion has completely healed, but sustained contact with the tubercle bacillus throughout adult life maintains hypersensitiveness to products of the micro-organism. The resulting immunity is limited and is overcome when the number of infecting tubercle bacilli is sufficiently great. Nevertheless, evidence that the earlier infection modifies subsequent disease is furnished by the characters of the adult type of pulmonary tuberculosis seen in association with the calcified scars of a first infection.

SIGNIFICANCE OF TUBERCULOUS INFECTION IN SCHOOL CHILDREN

The significance of the lesions that have been described varies widely.

A. Demonstrable tuberculous infection with the following characters is prevalent among healthy children and requires no special care to prevent its further development:

1. Infection revealed by the tuberculin test with no lesion demonstrable by roentgenologic examination.
2. Circumscribed pulmonary nodules that have undergone calcification.
3. Roentgenographically demonstrable tuberculosis of tracheobronchial lymph nodes, with the exceptions to be cited.

TABLE 6.—*Percentage of School Children Who Required Special Care*

	Prophylactic Care for Latent Tuberculosis of the Lungs		Treatment for Clinically Manifest Tuberculosis of the Lungs	
Years	Childhood Type	Adult Type	Childhood Type	Adult Type
5- 9	1.2	0	0.6	0
10-14	1.0	0.5	0.3	0.1
15-19	0.2	1.0	0.2	0.5

B. Children with the following conditions are in danger of tuberculosis that will undermine health and should receive special care in open-air schools, preventoriums or by other means to prevent further progress of the disease:

1. Latent tuberculous infiltration of the childhood type evident in roentgenograms, often associated with tuberculosis of tracheobronchial lymph nodes. In some instances, particularly in older children, these lesions are the scars of healed infection and do not require special care.
2. Tuberculosis of tracheobronchial lymph nodes with some calcification, recognizable by roentgenologic examination, (*a*) when the child is still in contact with open tuberculosis, (*b*) when the tuberculin reaction is intense, (*c*) when the lesions are unusually large or very numerous.
3. Latent tuberculosis of adult type.
4. Arrested pulmonary tuberculosis, notably in children who have been discharged from sanatoriums.
5. An active tuberculin reaction or an otherwise negligible tuberculous lesion recognized by roentgenologic examination in association with impaired health and conspicuous underweight, which are perhaps not referable to tuberculosis.

---

[10] Hamburger, F., and Monti, R.: München. med. Wchnschr. **56:** 449, 1909.

[11] Debré, Robert; and Cofino, E.: Ann. de l'Inst. Pasteur **44:** 12 (Jan.) 1930.

[12] Slater, S. A.: Am. Rev. Tuberc. **10:** 299 (Nov.) 1924.

[13] Report of an Ontario Survey of School and Preschool Children, Publication of the *Canadian Tuberculosis* Association.

C. Children who should receive sanatorium treatment or its equivalent are:

1. Children with tuberculous lesions accompanied by symptoms and physical signs referable to tuberculosis.
2. Children with latent lesions of the lung either of childhood or adult type that on repeated roentgenologic examination are found to be progressive.
3. Children with massive tuberculosis of tracheobronchial lymph nodes that has not undergone calcification.

An approximate measure of the number of children who required special care to protect them from tuberculosis may be obtained from tables 1 to 5 and are summarized in table 6.

The table excludes latent lesions of childhood type that are arrested (included in table 1). It does not include lesions of tracheobronchial lymph nodes that should receive special prophylactic care (listed under B 2) or arrested tuberculosis (B 4 and 5). The number of these lesions is relatively small, but with present knowledge it cannot be determined exactly.

Of the school children who were examined, from 1.5 to 2 per cent required special prophylactic care, and from 0.6 to 0.7 per cent should receive sanatorium treatment or its equivalent.

CONTROL OF TUBERCULOSIS IN SCHOOL CHILDREN

Demonstration of the frequency of advanced tuberculous infection among school children reveals one of the gravest problems of school hygiene, and at the same time suggests a promising and untried attack on tuberculosis.

The discovery of children with advanced tuberculous infection is by no means easy and requires a staff adequately trained in the use of technical procedures applicable to its detection. Routine roentgenologic methods are insufficient. Roentgenologic examination applied to the recognition of latent or clinically manifest lesions in children well enough to attend school requires methods specially adapted to examination of the chest, and the interpretation of plates demands experience together with intimate knowledge of the nature and clinical course of the disease. Furthermore, the application of roentgenologic methods to the examination of school children is costly. Even a simple procedure such as the tuberculin test is laborious, subject to many errors and, in the absence of essential precautions, may give misleading information. School surveys for the discovery of tuberculosis by these methods are inadvisable unless trained personnel and adequate facilities are available.

In the search for tuberculous infection, two procedures are available: 1. Examination by tuberculin tests and roentgenologic examination of all children known to be exposed to open tuberculosis; this method would be effective in proportion to the success of tuberculosis registration. 2. Roentgenologic examination of school children who react to tuberculin, precedence being given to groups of children, such as adolescent girls and Negro children, among whom the disease is known to be unusually frequent.

Measures recognized clinically to be the most effective in treatment are applicable at greater advantage to tuberculosis before it has impaired health. Many children in whom latent disease is recognizable require immediate sanatorium treatment or its equivalent. For children with grave latent lesions that are not progressive, avoidance of fatigue and regular periods of rest, sufficient nourishment, sunlight and fresh air will doubtless with few exceptions induce healing if further infection is excluded.

Preventoriums, open-air schools and summer camps to prevent tuberculosis in children believed to be in danger of developing it have been established on an elaborate scale in this country and in Europe. Records of the National Tuberculosis Association obtained through the kindness of Dr. Kendall Emerson show that there are in the United States thirty-two preventoriums with accommodations for 1,600 children; that fifty-seven preventorium units attached to sanatoriums provide for 3,400 children, and that the number of these institutions is rapidly increasing.[14] In 1926, the file maintained by the Elizabeth McCormick Memorial Fund showed that there are in 245 cities of the country 1,006 open-air schools with a capacity of 32,024. These figures are doubtless considerably larger now.

The aims of preventoriums and open-air schools vary considerably and are not as yet accurately focused on the medical problems with which they are essentially concerned. It is often stated without specific definition that they admit "pretuberculous" children. They are maintained for children "substandard in health," for it is vaguely assumed that any improvement in the health of children will prevent tuberculosis. Knowledge of grave latent tuberculosis of apparently healthy children accumulated during the last few years defines accurately a large part of the children who need prophylactic care to protect them from tuberculosis. It has shown that the discovery of these children is dependent on available technical procedures, and that preventive treatment must be guided by these procedures if it is to be effective.

Tuberculosis must be added to the list of diseases that can be successfully combated with the aid of public and other schools. Successful care of children with tuberculous infection will require modification of the school regimen, which should be adapted to special need. It is evident that much of the tuberculosis of adolescent children can be successfully combated by well known hygienic measures and modified high school courses that would preclude mental and physical fatigue. The undertaking is one that requires the cooperation of teachers, school administrations and physicians.

Early discovery, followed by suitable treatment, would arrest latent lesions and prevent clinical disease. Detection and cure of the latent infections of adolescent children can be used to prevent tuberculosis in early adult life when the disease is at its peak.

ABSTRACT OF DISCUSSION

Dr. Henry D. Chadwick, Detroit: In Massachusetts, where a hundred thousand school children were given the tuberculin test, the incidence of tuberculous infection was 28 per cent. It varied from this only about 1 per cent in each of the five years during which the work was done. A great variation was found in the incidence of infection in different communities and different areas in the same community. In one city of 60,000 people, the incidence of infection varied in different school districts from 11 per cent to 60 per cent. It was found, however, that whenever a group of 10,000 children was tested, regardless of where they lived, the average percentage of infection was approximately 28 per cent. Therefore, in comparing the studies made in different parts of the country, it is necessary to keep in mind the number of children tested before one can decide as to whether it is a true index of the amount of infection in the communities as a whole. There are nests of tuberculosis in city areas, and if tests are carried out in those places a high incidence of infection will be found which obviously will not be representative for the community. The childhood type of tuberculosis can be diagnosed only by the roentgen ray. Physical signs are usually absent in the childhood type of disease. The tuberculin test is the best means of determining what ones should be roentgenographed, as tuberculosis of both the childhood and the adult types are found frequently in children who are average weight or overweight. The physical examination, therefore, does not help to decide what children should have a roentgenogram to determine the presence or absence of tuberculosis. Four times as many cases of the childhood type of tuberculosis and twice as many cases of the adult type of tuberculosis are found among children with a history of exposure than in children giving no history of contact. Therefore, if a tuberculin test cannot be made on all children, at least all those should be tested in whom a history of exposure is obtained. The tuberculin test and roentgenogram of reactors should be used as a means of ferreting out other cases of tuberculosis.

[14] Murphy, M. E.: Cong. internat de protection de l'enfance, 1928, I, Sec. 3, 250.

Dr. Edward J. Rogers, Pittsford, Vt.: Five different groups are working on the problem of childhood tuberculosis. Dr. Opie, who has been associated with Dr. McPhedran, Dr. Hetherington and Dr. Landis; Dr. Walter Rathbun, superintendent of the Newton Memorial Hospital for Tuberculosis at Cassadaga, New York; Dr. J. A. Myers of Minneapolis, Dr. Henry D. Chadwick, who superintended the examination of school children in Massachusetts for several years and is now doing the same type of work in Detroit, and the group at Saranac. All these men are doing intensive work. A man who goes into schools hunting cases of tuberculosis should first be sent to one or more of these five groups, because if an enthusiast is turned loose with an x-ray apparatus and a vial of tuberculin, he is going to create havoc in the community. The x-rays will show that a large number of children are already infected, but I doubt the wisdom of broadcasting to the public that the child with a positive skin test and a seemingly positive roentgenogram has "tuberculosis" and will eventually have "consumption."

Dr. E. L. Opie, Philadelphia: I should like to say a word about the public health aspect of the problem. Tuberculosis must be added to the list of diseases that can be attacked with advantage in the schools. It is evident that if the methods known to prevent its further development are applied to tuberculosis in the latent stage, in which it is recognizable, a large part of the infections that occur in later life can be controlled. I do not think that this is an easy problem. I do not think it can be done without adequately trained personnel and facilities that are costly, or that it should be undertaken otherwise. But by this means a large number of children can be found and protected from further development of the disease. Three broad groups have been mentioned, the largest with insignificant infections, a second requiring prophylactic care, and a third with clinically manifested disease, who it seems to me and to my colleagues should have sanatorium treatment or its equivalent. I should particularly like to say a word about the children with latent, infiltrating lesions that require prophylactic care. These are indefinitely spoken of as pretuberculous or substandard children, with the vague idea that if one improves the children's health one prevents tuberculosis. To care for them, a large and rapidly increasing number of preventoriums, open-air schools and summer camps have been established. It seems to me essential that they focus their activities on the medical problem before them. They have not done that up to this time. They do not select the right children and they do not give them care under guidance that will tell whether or not the disease is advancing. It seems to me that by so doing these institutions will vastly increase their opportunities. There is an opportunity to recognize tuberculosis before it has undermined health and to recognize a large part of the adult type of tuberculosis in adolescence that will develop into active disease during early adult life, and that is the period in which tuberculosis takes most of its victims. I believe this question of the latency of tuberculosis is one of great public health importance.

EPIDERMOPHYTOSIS AND EPIDERMOPHYTIDS OF THE HANDS*

WALTER JAMES HIGHMAN, M.D.
NEW YORK

Mycotic hand eruptions frequently accompany similar ones on the feet. To explain this, Williams[1] and Bloch[2] independently advanced the hypothesis that the lesions on the hands, which are usually free of fungi, are dermatophytids secondary to foci on the feet which contain the organisms. Walthard[3] reported a case from Bloch's clinic, substantiating this view. In this patient fungi were present in lesions on the feet, and after a positive trichophytin test, a focal reaction took place in the hand lesions. Werner Jadassohn and Peck,[4] analyzing twenty-four cases, were able to support the belief that such concomitance existed between the foot and hand manifestations, the latter being trichophytids.

Subsequently Peck[5] was able to provoke the complete syndrome experimentally. In another patient with a demonstrated fungus infection of the feet and dyshidrotic vesicular lesions on the hands, he obtained a positive blood culture for fungi identical with those found on the feet, the hand lesions yielding no fungi on repeated examinations. The patient, moreover, gave a positive trichophytin reaction with a focal flare-up of the lesions on the hands. The organism isolated in this instance, as in the entire series of Jadassohn and Peck, was the epidermophyton of Kaufmann-Wolf. As stated, Peck experimentally reproduced the entire syndrome of epidermophytosis of the feet and epidermophytids of the hands in a human being. This fact, together with the recovery of the fungus from the circulating blood, established the original contention of Williams and Bloch, and is the first time a mycid has been experimentally engendered in a hitherto well person.

In the same article Peck published an account of a patient with primary epidermophytosis of one hand and ensuing epidermophytids on the other, as well as on one foot. This is the converse of what usually takes place. The experience furnishing the basis of the present paper corresponds closely with the foregoing one of Peck, save that the feet were free from lesions. The salient features of the history were as follows:

Mrs. M. K., aged 42, a musician, born in the United States, presented herself, April 18, 1928, with an itching eruption, chiefly on the hands and feet, but also with areas disseminated on the legs, thighs, arms, forearms and torso. Her general history was irrelevant.

On examination, lesions were found distributed as described. Those on the hands and feet were grouped vesicles on nummular, red, swollen disks on all surfaces of the fingers and toes and in the interdigital spaces. Isolated vesicles were also present. The usual consecutive lesions existed. Similar patches were situated on the arms, forearms, legs and thighs, but relatively farther apart than on the hands and feet, while an occasional patch could be seen on the torso. Under suitable local treatment most of the areas cleared up within sixteen days and the patient was not again seen for nearly a year.

5. Peck, S. M.: Epidermophytosis of the Feet and Epidermophytids of the Hands, Arch. Dermat. & Syph. **22**: 40 (July) 1930.

April 29, 1929, a severe recurrence having taken place during the preceding weeks, the patient was placed under indicated local treatment with short series of six weekly unfiltered one-fourth erythema doses of the roentgen ray. After a remission of several months the process again became active in November, 1929, with marked improvement by Jan. 26, 1930, after therapy identical with that already outlined. But another slight relapse set in by February 19. This, too, improved. April 21, a severe eruption broke out, but it was confined to the hands, which looked as follows:

On the dorsum of the left hand there was a nummular lesion about an inch and a half in diameter. It was irregularly oval, somewhat infiltrated and tended to central healing with a vesiculated periphery, although in its entirety the lesion scaled, crusted and was polycyclic. Fungi were easy to find in the vesicles. Smaller lesions of the same sort were present. There were also single "sago grain" vesicles on the sides of the fingers of the left hand, as well as on the back and palm. Scattered areas of superficial scaling existed, approaching the picture of dyshidrosis lamellosa sicca. Repeated microscopic examination of the scales and vesicles on the right hand as well as the scattered vesicles on the left were negative for fungi. April 21 a trichophytin test was moderately positive, after twenty-four hours. A focal reaction in the lesions on both hands appeared with crops of new scattered vesicles along the sides of the fingers during the next few days. Under intensive treatment of the primary lesion, healing of all the lesions took place.

In recapitulation, it may be emphasized that a patient with what originally, and over a period of three years, was a generalized eczematous eruption, finally, after many remissions and relapses, acquired a condition confined to the hands. One and only one of these lesions, in spite of repeated study of the rest, was found to contain fungi. These lesions flared up focally after a positive trichophytin test, beginning to heal only when the infected forms had responded to treatment. Thereafter their resolution was rapid.

Disregarding its etiology, the eruption in this patient would have to be classified as a nummular, vesicular, squamous and crusted eczema, with distinct elements on and near the digits and on the palms and soles of dyshidrotic dermatitis, or eczematized pompholyx. At the outset, the eruption, having had a tendency to generalization, would have been classified as a generalized eczema as well. In view of the ultimate observations many, if not all, of the far flung lesions must have been trichophytids. It seems likely enough, in the light both of Peck's experimental reproduction of such a syndrome and of his having isolated the epidermophyton from the circulating blood, that in this woman, too, there must from time to time have been a phytemia. To construe these phenomena as purely toxitrichophytids does not appear warranted, considering the work of Jadassohn and Peck together, and Peck alone.

A most unusual feature of the case, and indeed the one that chiefly impelled its publication, was the fact that trichophytids could arise solely on the hands from hand rather than foot infection. The only approach to this state of affairs is in Peck's case of hand and foot trichophytids associated with a hand infection. The common order of events is precisely the reverse. It is a matter of speculation just why the hands appear so much more susceptible to this form of trichophytid than any other part of the body. No ready explanation suggests itself.

The practical significance of this experience and related ones in terms of therapy is that it probably is important to ascertain in this disease which lesions are infected ones and which are trichophytids, since the parasites, fed from the former into the circulation, provoke the latter. Morphologically the two types of lesions are similar except that trichophytids are more irregularly distributed and single, on account of their hematogenous origin, while the infected lesions tend to spread peripherally. Therefore it is essential to make the microscopic differentiation so that antiseptic treatment may be applied to the proper sites with the idea of cutting off the source of trichophytid production. At first the irritation to the infected areas may actually increase the production of trichophytids, as has been clinically substantiated (Williams, Peck, Jadassohn). This soon subsides, however, as in the patient here described. Moreover, it may be emphasized that clinically this disease is what was called eczema, and formerly it would have been treated as such without avail. It is distinguished from other types of eczema, both those due to the allergic mechanism and those of unidentified origin, only with respect to the fact that the precipitant is a fungus or the toxins of such a fungus, behaving as eczematogens. It is likely enough that clearer understanding of the nature of this process may further illuminate the problem of the nature of eczema, whatever the precipitant.

853 Seventh Avenue.

ABSTRACT OF DISCUSSION

Dr. Paul A. O'Leary, Rochester, Minn.: Contributions in the form of well studied case reports are valuable aids in crystalizing knowledge of the ringworm problem, as well as aiding in the clearing of the eczema maze. I, too, believe in the existence of a palmar trichophytid in association with epidermophytosis of the feet, and feel grateful to Williams and Bloch for having called attention to it. I also believe that pompholyx or dyshidrotic eczema is still an entity with no etiologic relationship to fungi. The hypothesis that pompholyx is a neurogenic manifestation is still tenable to me. The effect of chronic nervous exhaustion states as a factor in the production of pompholyx was forcibly demonstrated several years ago when bank failures throughout the Northwest became an everyday occurrence. Although fungi have been recovered from the blood stream, I do not believe that this finding has received as yet a conclusive interpretation. It is true that a clinical analogy can be drawn between tuberculosis, syphilis and "phytemia," as Dr. Highman calls the blood stream infections with the trichophyte. The inoculation or chancre phase, the disseminated phase and the latent period are readily seen in all three diseases. Nevertheless, the significance of the finding of the trichophyte in cultures of the blood has not proved the pathogenesis of the organism. The study of the local skin chemistry, as for example the estimation of the individual cell hydrogen ion concentration I believe will disclose more of the clinical phenomena than will cultures of the fungi from the blood stream. Trichophytosis is frequently a self-limited disease; likewise exacerbations of the primary focus as well as the appearance of palmar trichophytids are not uncommon following treatment of the original lesion. These are evidence of changes in cutaneous allergy as the result of changes in the local chemistry of the skin, rather than secondary to a generalized blood stream infection.

Dr. Joseph Grindon, St. Louis: Regarding these eruptions, trichophytids, epidermophytides, or whatever one wishes to call them, that occur on the palms and sometimes on the feet, I wish to bear out what Dr. O'Leary has said about the existence of a nervous influence. I have seen this exemplified many times. As I stated on a former occasion, it has for many years been my practice—and was before Sabouraud showed the mycotic organisms in this disorder—to administer strychnine in small doses, with great benefit to the patient, at least temporarily. There remains a question as to how much in these cases is due to what has been called anaphylaxis and allergy. Coca has come to some rather startling conclusions about those processes. He does not admit that anaphylaxis ever occurs in the human subject and is of the opinion that the term allergy should be dropped as being without meaning. I am reminded of an episode that occurred in France at a recent meeting of the Société de dermatologie, when Ravaut demonstrated a generalized eruption consequent on a yeast infection in the axilla. Milian, who was president, expressed the belief that all those things which had been called eczema might be considered as due either to contact with some irritating substance or to hematogenous conveyance of material there absorbed. Darier, commenting on that in the *Annales,* said that this conception might point a little nearer to the truth, but as to its being the truth he did not believe a word of it. He seemed to have no more respect for our conception of allergy than has Coca, for he came back to the old term "idiosyncrasy" and said that when physicians talk about allergy and anaphylaxis they have only invented a new kind of slang.

Dr. George M. MacKee, New York: The weight of scientific evidence is in favor of dermatophytid being due to sensitization to fungus products from a focus, usually between the toes. There is a question, however, whether there is any difference in the mechanism of production in dermatomycosis and dermatophytid. On the assumption that the fungus obtains its foothold between the toes, if a local eruption occurs it is because the tissue has become susceptible—allergy. This is dermatomycosis. The organisms enter the blood, tissues in other parts of the body become susceptible, and an eruption occurs. This is dermatophytid. The fact that conventional fungi are so rarely found in dermatophytid might indicate that it is due to some toxic chemical product. On the other hand, the mosaic fungus is often found in dermatomycosis and dermatophytid, especially in "pompholyx," and always in keratolysis exfoliativa. The mosaic fungus is considered an artefact by many, but it may be a degenerated or attenuated fungus, a harmless organism, a saprophyte, a weak pathogen or a strong pathogen depending on the environment—the defensive mechanism of the host. While there may be a fundamental difference between dermatomycosis and dermatophytid, it seems preferable to retain the terms at least until greater knowledge is available.

Dr. Jack W. Jones, Atlanta, Ga.: In our section of the country these cases constitute a very large group, probably the largest we have, and the hand eruptions are the bane of my existence. From the standpoint of there being a tricophytid, it has always seemed to me that if they are treated correctly these eruptions should sooner or later respond to treatment, but this has not been the experience with us. That is why after reading and hearing of the different work that has been done I am doubtful about it. In the majority of our cases after we do everything we can the condition of the hands remains the same.

Dr. Samuel C. Ayres, Jr., Los Angeles: Concerning the remarks of Dr. Jones and Dr. Highman regarding microscopic examinations, I think these can be brought together very nicely. It is my custom to check microscopically all patients to demonstrate the infected areas. By astringent preparations and the roentgen ray the noninfected areas clear. I cannot help but feel that the microscope is a most important agent in the diagnosis of these cases. Not only is each area checked microscopically on the patient's first visit, but it is checked every week or ten days until the patient is discharged. It is easy to clear them up clinically, but in many instances they are still microscopically infected. The area that might be considered clinically as normal still shows infection microscopically. I think one point not sufficiently emphasized is that there are successes and failures. Every one has his favorite method of treating but usually nothing is said about what shall be done with shoes and other wearing apparel, other than that it shall be thrown away. It has been definitely shown that fumigation with formaldehyde will kill the fungus. Patients are advised to sterilize their bedrooms and all clothing which might come in contact with the hands and feet.

Dr. Walter J. Highman, New York: I do not know whether there is such a disease as pompholyx; I think there may be. I am not partisan to fungi, I am not loyal to them, I do not approve of them, but I do not maintain that they are the only cause of an eruption that looks like pompholyx. Dr. Grindon might put me in the class with those who arraign allergy as applied in clinical terminology. The term does not make any difference; after all, people get a disease because they are susceptible to it and what susceptibility is called does not matter. If any one wants to call it anaphylaxis instead of susceptibility, it is all right so far as I am concerned. The fact that one individual gets an infection and the other does not only shows that one is sensitive and the other is not. I cannot get much worked up about whether Coca or I myself flouted the concept of anaphylaxis. What if he or I do or do not? What does it matter so long as it is known that only certain fungi can make people sick and do make them sick? I do not agree that the neurodermitides are necessarily fungous manifestations. I do know it is possible to recover the organism from the blood stream, but not always. It is not the local patch of tricophytosis that causes a widespread dermatitis but allergy, so called, or what you will, in the skin to which eczematogens arrive, a sort of percutaneous or intradermal test performed by nature itself. That is all trichophytids can be. Whether due to the organism or its toxin does not matter so long as the facts are found out. I have no time to isolate the organisms from each lesion on a patient. I do not hold any great plea for descriptive dermatology, but some things can be distinguished descriptively. A distinction can be made with some certainty between active tinea and trichophytids. I am quite sure that if there is anything at all in the doctrine of focal infections this is a good example of focal infection, and that if the foci can be controlled the far-flung disease can be controlled.

THE FUTURE OF THE DIABETIC CHILD*

PRISCILLA WHITE, M.D.
BOSTON

The twenty thousand children in the United States who today are diabetic or potentially diabetic compel us to ask the question "What does the future promise the diabetic child?" Growth, development, and duration of life are no longer the outstanding problems of the diabetic child treated with insulin. In the nineteen months ended Feb. 1, 1930, among 423 children living in that period there were only 10 fatalities, and 5 of these were due to coma untreated. The growth in height and weight was essentially normal and but one girl over 20 years of age has failed to mature.

Yet with increasing age the diabetic child who has demonstrated his ability to carry on the normal functions of childhood and youth faces a new problem in the possible transmission of his disease. The hereditary taint in the diabetic child is evident. Repeated questioning and the fact that diabetes may be latent in an adult member of the family and not appear until after it has occurred in the child have increased the percentage of heredity in our children 100 per cent. Whereas the fatal cases showed a history of heredity in 20 per cent, in the living cases the heredity has steadily risen year by year until it has reached 40 per cent.

But is the inheritance of diabetes necessarily and always a handicap? The potential diabetic type is in itself favorable. At the onset of his disease the diabetic child is characterized by precocity. His physical and roentgenologic ages are eighteen months in advance of his chronological age. His mental age is eight months in advance. Although after years of duration of the disease there is some evidence that physical growth may be retarded, the stature of the child does not fall appreciably below the standard average and, what is of more importance, mental growth continues above the normal average.

---

* From the Joslin Diabetic Unit, New England Deaconess Hospital.
* Read before the New York Academy of Medicine, March 18, 1930.

Overgrowth is an almost constant characteristic of the prediabetic child. It has been reported in over 90 per cent of our own children measured within three months of onset, in 88 per cent of Ladd's diabetic children and in the majority of the children studied at the Children's Hospital, Boston, and in the seventy-one children studied by Rabinowitch. The significance of overgrowth is puzzling.

Overheight in the child, we believe, corresponds to obesity in the adult. Just as obesity need not reach extremes before the onset of diabetes in the adult, overheight need not reach extremes before onset of diabetes in the child. As to the cause of overheight one can only surmise. Overheight may be the result of optimum nutrition or infections with their subsequent gains in length. It is true that we have found that histories of recent infections are lacking, but we cannot rule out the latent results of infectious diseases. Overgrowth may be associated with hyperactivity of the other glands of internal secretion, particularly the pituitary. Since the etiology of diabetes in the child is still a mystery, the possible combination of an hereditary taint and an environment producing maximum growth must be considered.

The investigation of the pathologic changes in the tissues of the diabetic child, which may be attributed to the disease or its treatment, constitute the second problem. It would be tragic indeed to keep the child alive to be disfigured, to succumb to tuberculosis or to become crippled and blind. For evidence our entire series of patients is available, consisting of 625 diabetic children treated from the years 1898 to 1930 to show whether such tragedies are encountered. Of these children, 212 are dead and 413 are living. The group represents thirty years of medical practice and thereby offers material which is unique in the relatively large numbers of cases of long duration. The series of necessity consists of many patients in whom a variety of methods of treatment, quite different from the methods of today, have been employed. The transition of treatment has been more or less gradual, but in order that we and others interested in this problem may compare the data fairly, we have divided our living children into two groups: the 81 children whose disease began before the use of insulin was begun in our clinic, and the 332 children seen subsequently.

The skin of some of the diabetic children of both these groups has shown xanthosis. Although this is disfiguring, it is not of great importance and fortunately is remediable. This characteristic yellow pigmentation about the tissues of the mouth, the palms of the hands and the soles of the feet is undoubtedly due to the large quantities of vegetables in the diet. Xanthemia as well as xanthosis has occurred in these cases.

Xanthoma diabeticorum has proved a rare complication and has been recognized but three times in our group. In two of these cases the onset of diabetes antedated insulin. Two patients were coma offenders and in these the cholesterol of the blood was studied and found to be markedly increased. Improvement in skin lesions occurred shortly after the fat and total caloric values of the diets were decreased. The associated hypercholesterolemia also diminished but had not in the most recent analysis reached what we accept as the normal level, 230 mg. per hundred cubic centimeters.

Tuberculosis or tuberculous lesions have occurred in 10 of the total 625 children. It was present in 7 children whose diabetes began before Aug. 7, 1922, the date of our first use of insulin, and in 3 children whose onset was after that date.

The eyes of the diabetic children have so far proved invulnerable. In our only living patient with cataracts, the diagnosis was made in the seventh year of the disease, at the same time that she was found to have pulmonary tuberculosis and calcification of the vessels of the legs. Her blood also shows an increase in cholesterol. As for her diet and insulin in the past we have no idea, as evidenced by the fact that she has been in coma or near coma on five occasions. Three of the fatal children—and these were children who had never had insulin—had cataracts. It is gratifying that, of the children in whom routine examinations of the eyes have been made, but one child has had a condition more serious than muscular unbalance. The child who is the exception has retinal hemorrhages as well as cataracts.

Calcification of the blood vessels of the legs has occurred in eleven diabetic children, all of whom had onset of diabetes prior to August, 1922. The average duration of diabetes at discovery of sclerosis was seven years. The ratio of carbohydrate to fat in the diets of these patients varied from 1 Gm. of carbohydrate to 3 Gm. of fat and from 1 Gm. of fat to 3 Gm. of carbohydrate. It would be wrong to draw conclusions from these figures, because of the unreliability of most of these patients.

The cholesterol of the blood of these children with calcified arteries in the legs is presented here to add to the material already available, but it is, we consider, insufficient for conclusions. In five of these children the cholesterol of the blood was examined prior to the appearance of sclerosis. In two the cholesterol was above 230 mg.; in three it was persistently below. That hypercholesterolemia is or is not a precursor of arteriosclerosis in the child, therefore, we cannot say; nor is it evident from our data available at the present time that the presence of cholesterol in the blood over a period of years is harmful. Twenty-six of 100 children without obvious disturbance of fat metabolism such as coma or xanthoma had percentages of cholesterol of the blood at one or another analysis above 230 mg., yet in but four of these have complications occurred up to date. These complications were cataracts, tuberculosis and arteriosclerosis.

The average proportion of cholesterol in our group was 212 mg. per hundred cubic centimeters. This includes specimens of blood examined both in the fasting and in the postprandial states. Twenty children recently examined showed cholesterol above 230 mg., but in only fourteen of them is the cholesterol not approaching normal levels.

[illegible] we know that the complications associated with diabetes in the adult can occur in the child, in our own experience we have found that it is the diabetic child treated with the inadequate methods of yesterday who has developed cataracts and arteriosclerosis.

The adequate treatment of the diabetic child is a most difficult problem and tests the skill of any physician. The difficulty lies not so much in the severity of the disease as in the four variables that exist. Of these, the first is the reliability or nonreliability of the child, second is the emotional stability, third the variability of exercise, and fourth the inevitability of intercurrent infections.

Adequate treatment, we believe, implies a diet, first, in which the caloric value is such that growth and development neither exceeding nor falling below normal will occur, and, secondly, in which the partition of carbohydrate, protein and fat is so adjusted that after years of treatment it will neither produce injurious effects on the various bodily system nor increase the severity of the disease. It may be true and probably is true that several possible dietetic combinations of carbohydrate, protein and fat will answer these requirements. We can only say from our experience that a diet in which the prescribed caloric value was at least 50 per cent above the basal metabolism and one in which at least 25 per cent of the total calories were in the form of carbohydrate, thus presupposing the use of insulin, and from 10 to 15 per cent in the form of protein, has been found to answer the first two of the three requirements.

Our children with the longest duration of treatment are the children treated by Dr. Joslin in the Allen era with few calories and relatively low quantitites of carbohydrate. These children have gained tolerance for carbohydrate. This method of treatment was therefore not injurious to the pancreas and it kept alive a group of fifty diabetic children, whereas children treated by other methods died. Stunted growth occurred in the younger children as the result of caloric insufficiency. Today when from 25 to 50 per cent of the total calories are taken in the form of carbohydrate and when the prescribed diet is not less than 50 per cent above the basal metabolism, normal rates of growth occur and increasing severity of diabetes after the initial stabilization is the exception rather than the rule in the five-year case. The year 1930 represents the seventh year of insulin. One may therefore institute comparisons between the preinsulin children who began to show complications at 7 years and our children who have had insulin seven years. There are fifty-nine of the latter cases in our group. Only ten of these have had roentgen examinations of the legs. None have shown evidence of sclerosis, whereas one in three of the preinsulin children studied had evidence of calcification of the vessels of the legs.

The former advocates of high fat and high caloric diets report normal rates of growth in diabetic children but state that the disease becomes increasingly severe. Individual interpretation of data, however, must be considered as there are no established rules for measuring gains or losses of tolerance. A full decade of time will be necessary to tell which combination of diet, high carbohydrate, a moderate amount, or a low carbohydrate diet, will best answer all the requirements during the course of years. We believe that, until we have the evidence, it is far safer not to go to extremes, neither to adopt the low carbohydrate-high fat diet, which appears to lower tolerance for carbohydrate, nor to adopt the reverse diet, which fails to protect and spare the pancreas which is diseased; and, above all, we would avoid high calories to prevent excess of growth, which seems to be a precursor of diabetes in the child.

The diabetic child has taught us lessons of great importance: first, that heredity is an undoubted etiologic factor in diabetes; second, that the child affords new evidence to the theory that overnutrition is a precursor of diabetes; and, third, that cataracts and arteriosclerosis can occur in pure diabetes under the age of 20 years. Nevertheless the possibilities of combating the taint of heredity and an environment producing maximum growth are apparent while the evidence of the decreasing severity of diabetes, the absence of its complications in the child treated with insulin from the very onset, and the actual lack of organic disease of the pancreas offer limitless hope for the future of the diabetic child.

CHANGES IN THE RESPIRATORY MECHANISM FOLLOWING PHRENICECTOMY

WALTER I. WERNER, M.D.
PONTIAC, MICH.

In the past year the literature has been replete with reports stressing the importance of phrenicectomy in the treatment of pulmonary tuberculosis. It has been observed that phrenic neurectomy is not attended with any great danger in man.

Lemon,[1] in a series of experiments on normal dogs, concluded that either unilateral or bilateral phrenicectomy was attended with slight risk and did not produce demonstrable impairment of function in general or of respiratory function in particular. Compensation was sufficient to overcome the loss in function of half or the whole diaphragm of the dog, and the animal was able to carry on its usual activities without embarrassment or dyspnea.

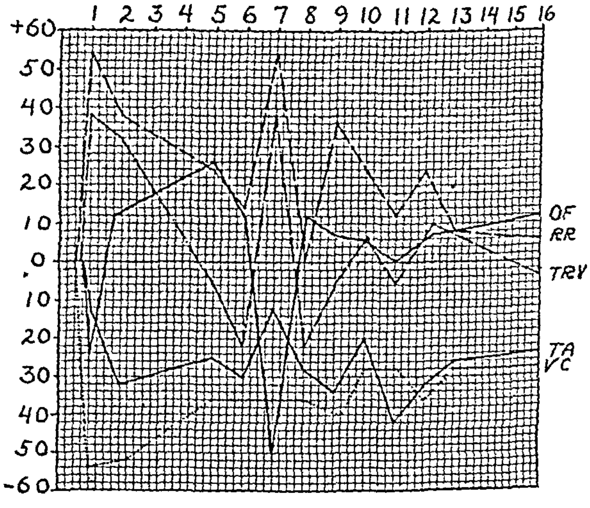

Chart 1.—Changes of the respiratory mechanism of a patient in group 1: In charts 1, 2 and 3, *O F* indicates oxygen fraction; *R R*, rate of respiration; *T R V*, total respired volume; *T A*, tidal air; *V C*, vital capacity. The figures on the top of each chart represent the days following operation. The figures at the left side represent the percentage increase or decrease of the oxygen fraction, rate of respiration, tidal air and vital capacity.

Andrus[2] made studies of the changes in the cardiorespiratory mechanism in dogs, following hemiparalysis of the diaphragm. The experimental data collected were summarized as follows: 1. The pulse and respiratory rates increased about 10 per cent. 2. There was a moderate increase (about 25 per cent) in the amount of blood flowing through the lungs per minute, and an increase of about 15 per cent in the pulse volume. 3. The tidal air volume and respiratory volume were decreased by about 20 and 15 per cent, respectively.

---

[2] Andrus, W. D., and Wilson, J. D.: The Effects of Closed Pneumothorax and Phrenicectomy on the Cardiorespiratory Function, Arch. Surg. **19**: 1205 (Dec., pt. 2) 1929.

My object in the present study was to note the changes in the respiratory mechanism following phrenicectomy in man. Observations were made before and after operation on a group of twenty patients with advanced unilateral pulmonary tuberculosis. They were all afebrile but on strict bed rest. Before each study they fasted twelve hours. The McKesson recording metabolor, which is based on the closed circuit method for the determination of the respiratory exchange, was used. Here the subject rebreathes oxygen from a closed space, the carbon dioxide being absorbed by soda lime. Tracings were made of each patient's breathing over a period of six minutes. The patient's respiratory curve was recorded in red ink on a paper ruled in one direction, in minutes and subdivided into tenths; and in the other, in liters and subdivided into tenths. By the rulings of the chart one is able to read directly the volume of tidal respirations, the rate per minute, and the vital capacity, in addition to the rate of oxygen absorption. These readings were all corrected for changes of temperature and barometric pressure. The basal metabolism was calculated according to the formulas of Du Bois, while the total respiratory volume was determined by the rate of respiration times the tidal air volume multiplied by the time. Two or more tracings were recorded in each case before operation in order to establish a base line. Following the phrenicectomy, records were made at intervals of two days until the vital capacity started to return to what it was before operation, and then biweekly until the vital capacity reached its preoperative level. The first eight days after operation presented the most essential changes. These are reported and illustrated by graphs.

In none of these cases was there any appreciable change in the pulse rate or basal metabolic rate as a result of the operation.

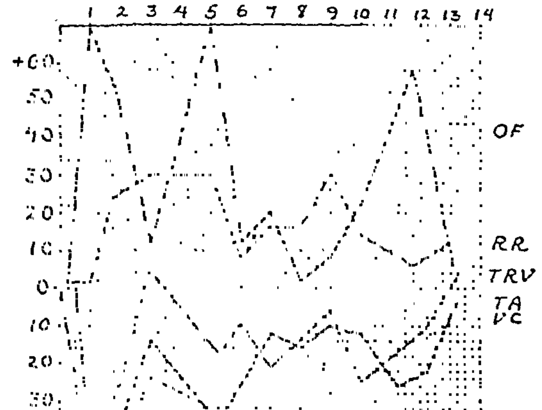

Chart 2.—Changes of the respiratory mechanism of a patient in group 2.

The vital capacity is the maximum amount of air that can be inspired at the end of forced expiration. Garvin, Lundsgaard and Van Slyke[3] have found the vital capacity definitely reduced by pulmonary tuberculosis. In the group of patients studied, the vital capacity ranged before operation from 42 to 64 per cent, the average being 50 per cent of the theoretical normal as judged by Myers'[4] standing height standards. The average decrease in the vital capacity of all patients following phrenicectomy was 32.6 per cent. The maximum decrease occurred within the first forty-eight hours. In five of the patients the vital capacity decreased to 23 per cent of the normal theoretical amount. In none of the patients was there any evidence of cyanosis or dyspnea. The vital capacity returned to what it was before operation within from two to eight weeks.

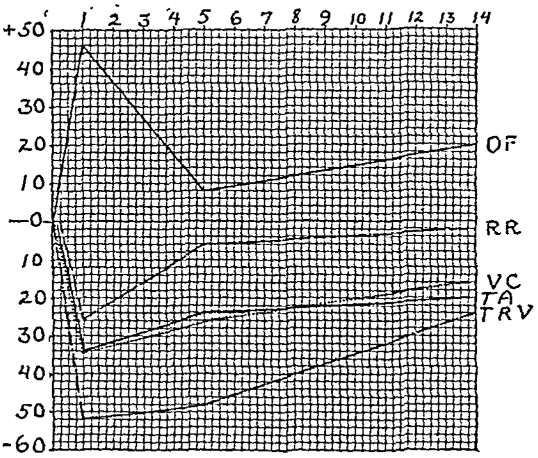

Chart 3.—Changes of the respiratory mechanism of a patient in group 3.

The tidal air is that volume of air which is inspired and expired during normal respiration. In all but one patient it decreased. The oxygen consumption remained practically unchanged. Considering the decrease in the vital capacity and tidal air while the oxygen consumption remained practically unchanged, some compensating mechanism is obviously necessary to provide for the unaltered oxygen supply. Yates[5] found a constant relationship between the volume of ventilated air, the area of alveolar epithelium, the expanse of capillary endothelium and the amounts of blood needing aeration. This relationship depends on the utilization of the inspired air. It is the ratio expressed in percentage of the oxygen retained to the total respired air and is designated in this paper as the oxygen fraction. This compensation for the unaltered oxygen consumption took place in three different ways. In six patients the compensation for the decreased tidal air (10.5 per cent average) was achieved by an increase in the respiratory rate only. This increase was 28 per cent in average. Since the oxygen fraction decreased (13 per cent average) and the total respired volume increased 11 per cent, this means that these patients performed more respiratory labor while utilizing the inspired air less efficiently.

In seven patients the compensation was achieved by an increase of the respiratory rate (average 22 per cent) and by a better utilization of the inspired air. A larger percentage of oxygen was retained from the respired air. The oxygen fraction increased 28 per cent in average. The tidal air was much decreased in this group (average 35 per cent).

In seven patients the compensation was achieved only by a more efficient utilization of oxygen. The average increase in the retained oxygen fraction was 35 per cent. This better utilization of the inspired air accomplished the necessary compensation without increased respiratory labor. The average decrease of the tidal air in this group was 29 per cent.

COMMENT

The most marked changes in the respiratory mechanism took place within the first eight days following hemiparalysis of the diaphragm. The oxygen consumption remained practically unchanged. With the reduction in the tidal air and vital capacity, some compensating mechanism is obviously necessary to provide for the unaltered oxygen supply.

In group 1 during the period of compensation a greater volume of air was ventilated in order to obtain the required amount of oxygen. The total respired volume increased 11 per cent. This adaptation was achieved through the increased respiratory rate. The respiratory labor was increased.

In group 2, the compensation was achieved by a better utilization of the inspired air. A larger percentage of oxygen was retained from the respired air, the increase being 28 per cent in average. Though there was an increase in the respiratory rate (average 22 per cent), the balance was maintained by a decrease in the respired air (average 22.5 per cent). The respiratory labor was not increased.

In group 3, the compensation was achieved only by a more efficient utilization of oxygen. The average increase in the retained oxygen fraction was 35 per cent. This better utilization of the inspired air accomplished the necessary compensation while the respiratory labor was decreased.

In this series of patients the respiratory labor was found to increase in 30 per cent and to remain unchanged or to decrease in 70 per cent following phrenicectomy.

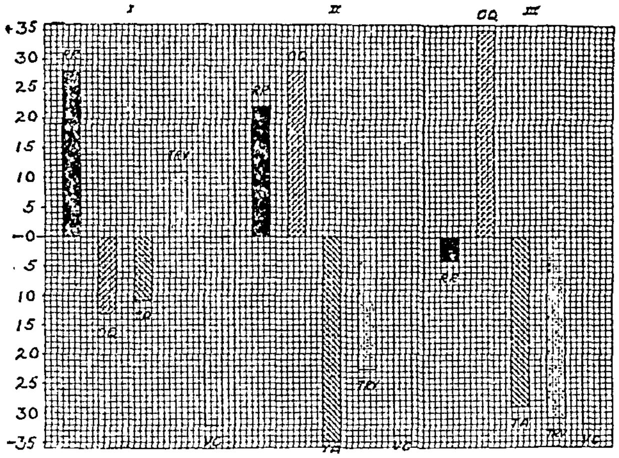

Chart 4.—Behavior of the respiratory mechanism in the three groups. The figures at the top indicate groups 1, 2 and 3. The figures at the left side indicate the percentage increase or decrease of the rate of respiration, total respired volume, tidal air, oxygen quotient and vitay capacity. *O F* or *O Q* indicates *oxygen fraction*; *R R, rate of respiration*; *T R V*, total respired volume; *T A*, tidal air; *V C*, vital capacity.

It is probable that the better utilization of the inspired air in groups 2 and 3 depends on the physical theory of respiration. The physical theory of respiration assumes that the gaseous exchange in the lungs and in the tissues takes place in accordance with the physical laws of diffusion of gases. If a permeable membrane separates two volumes of any gas or two solutions of any gas at different pressures, the molecules of the gas will pass through the membrane in both directions until the pressure is equal on the two sides.

SUMMARY

Studies of the changes in the respiratory mechanism following phrenicectomy were made on twenty patients. The data collected may be thus summarized:

1. The vital capacity decreased in all patients.
2. In all but one patient the tidal air decreased.
3. The oxygen consumption remained practically unchanged.
4. This compensation took place in three different ways: (*a*) In group 1 the compensation was achieved by an increase in the respiratory labor only. (*b*) In group 2 the compensation was achieved by a better utilization of the inspired air with no change in the respiratory labor. (*c*) In group 3 the compensation was achieved only by a more efficient utilization of oxygen with a decrease in the respiratory labor. There was no evident correlation between the extent and the pathologico-anatomic type of the lesions and the mechanism of compensation following the operation.

ENDOMETRIOSIS

A REVIEW BASED ON THE STUDY OF ONE HUNDRED AND EIGHTEEN CASES *

FLOYD E. KEENE, M.D.
AND
ROBERT A. KIMBROUGH, Jr., M.D.
PHILADELPHIA

For many years endometrium-like tissue has been recognized as occurring in the ovary, on the surface of the uterus, in the rectovaginal septum, in the umbilicus and elsewhere in the pelvis. To Sampson, however, belongs the credit for elucidating the pathologic nature and life history of the condition. In typical instances this tissue is histologically and functionally identical with the endometrium; its reaction to menstruation is evidenced by swelling, pain and tenderness at the menstrual periods as the result of the escape of blood into the glandular spaces.

The formation of decidua in these misplaced glands has been shown to occur during intra-uterine pregnancy, and atrophy of these formations commonly follows cessation of ovarian function. On these facts are based the interpretations of the symptomatology and the principles underlying treatment.

SYMPTOMATOLOGY

The literature is replete with contributions dealing with the etiology of endometriosis, but it is remarkedly poor in those presenting a comprehensive analysis of a comparatively large series of cases. The conclusions of this paper are drawn from a study of 118 cases of endometriosis admitted to the gynecologic department of the Hospital of the University of Pennsylvania.

Because of wide variation in the pathologic manifestations, discussion of the symptoms necessitates division into three main groups: (1) intraperitoneal endometriosis, which is the most common manifestation, including lesions of the ovaries, tubes, uterus, pelvic peritoneum and intestines; (2) adenomas of the rectovaginal septum, and (3) transplants or fistulas located in the umbilicus or laparotomy scars.

Intraperitoneal Endometriosis.—The symptoms are not uniform because of the frequency of complicating pathologic changes in the pelvis. Small implants on the ovary, uterus, intestines or the peritoneum of the culdesac are often symptomless, but with the development of large ovarian hematomas, which are invariably densely adherent, or with invasion of neighboring structures, a clinical picture is presented that often permits of a definite diagnosis.

---

* Read before the Section on Obstetrics, Gynecology and Abdominal Surgery at the Eighty-First Annual Session of the American Medical Association, Detroit, June 25, 1930.

TABLE 1.—*Location of Endometrial Lesions in 118 Cases*

Ovary		110
Unilateral	63	
Bilateral	47	
Rectovaginal septum		6
Umbilicus		2*
Laparotomy scar		1

* In one of the umbilical cases there was also ovarian involvement.

Excluding the cases of symptomless implants discovered at the time of operation for some other condition, 109 patients with ovarian endometrioma have been subjected to operation and one patient is under observation.

Associated Pathologic Manifestations.—The presence of complicating disease is a striking feature of this series. Uterine myomas were found in 55.4 per cent, a chronic salpingitis in 20 per cent, and adherent retroflexion in 14.5 per cent. King[1] reports myomas in 22 per cent, adherent retroversion in 21 per cent and evidence of previous inflammation in 39.7 per cent. In Smith's[2] series, myomas were present in 41.6 per cent and adherent retroversion was present in 25.8 per cent.

TABLE 2.—*Associated Pathologic Manifestations in Ovarian Endometriosis*

Myoma uteri:		
Uncomplicated	44	55.4%
With pelvic inflammatory disease	10	
With retrodisplacement	4

Pseudomucinous	1	
Parovarian	2	
Retrodisplacement of uterus	12	
Chronic pelvic inflammatory disease	12	
Adenomyoma uteri	4	
Omental cyst	1	
None	25	
	118	

Age Incidence.—With but rare exceptions, the lesion occurs during the years of menstrual function. Our youngest patient was 22 and the oldest 60. Only two patients had passed the menopause. The incidence by decades is as follows: third, 18.6 per cent; fourth, 49.1 per cent; fifth, 25.4 per cent, and sixth, 6.8 per cent.

TABLE 3.—*Age Incidence of Endometriosis in 118 Cases*

Youngest	22
Oldest	60
By decades:	Per Cent
20-30	18 6
30-40	49 1
40-50	25.4
50-60	6.8

Only two patients had passed the menopause.

Sterility.—The extensive alterations resulting from the lesion itself as well as the complicating abnormalities render sterility a prominent symptom. Seventy per cent of our patients were married, with a sterility incidence of 40.9 per cent. Of those patients who had borne children, the average interval elapsing since the birth of the last child was 9.5 years. In Donald's[3] series, 40 per cent were sterile and only one patient had given birth to more than four children. Smith reports sterility in 20.6 per cent of 159 cases and Shirer[4] noted this symptom in 84.2 per cent of his series of 30 cases.

Menstrual Anomalies.—Ovarian endometriomas per se produce no uniform alteration in menstruation.

TABLE 4.—*Study of Fertility in Married Patients*

	Number	Years	Per Cent
Patients studied	83	..	....
One or more pregnancies	..	..	59.1
Sterile	..	..	40.9
Patients giving length of time since last pregnancy	39	..	....
Variation of interval	..	1 to 25	....
Average interval of sterility	..	9.5	....

A summary of our observations is given in table 5. The menorrhagia group comprised forty-eight patients, and in thirty-two of these uterine myomas were present, so that in only sixteen might the symptoms be ascribed to an ovarian dysfunction. King found that in 75 per cent of his patients an existing menorrhagia could be definitely accounted for by an associated uterine lesion. Donald, Smith and Shirer also are reluctant to attribute menstrual irregularities to the ovarian involvement. It seems justifiable to conclude, therefore, that profuse menstruation is usually a symptom of the complicating lesion rather than of the endometrioma itself.

Dysmenorrhea.—This symptom is commonly present, although we found that 40 per cent of our patients gave no history of menstrual pain. Dysmenorrhea dating from puberty with no increase in severity nor alteration in type was noted in 11.2 per cent; 49.1 per cent gave the history of an acquired or increasing dysmenorrhea, the pain being premenstrual in type and persisting through the first day or two of the flow. With invasion of the bladder, rectum or rectovaginal septum, pain and disturbed function occurred only at the menstrual periods or became greatly exaggerated at this time.

TABLE 5.—*Incidence of Menstrual Disturbance in Connection with Endometrioma*

	Per Cent
No disturbance	41.5
Menorrhagia	44.1
Metrorrhagia	8.4
Scanty flow	2.5
Amenorrhea	1.7
Postmenopausal amenorrhea	1.7

Donald found dysmenorrhea present in 70 per cent of his patients, being of the acquired type in 50 per cent. Smith reports this symptom in 60.5 per cent of his series and King in "over 50 per cent" of his cases. Of King's patients who complained of rectal pain during menstruation, an endometrioma of the rectovaginal septum was present in 75 per cent.

Intermenstrual Symptoms.—The majority of our patients did not complain of symptoms referable to the pelvis between the periods. In 45 per cent, however,

2. Smith, G. V.: Am. J. Obst. & Gynec. 17: 806 (June) 1929.
3. Donald, A.: Brit. M. J. 1: [illegible], 1922.
4. Shirer, J. W.: Canad. M. A. J. 18: 151 (Feb.) 1928.

there was intermenstrual discomfort or actual pain in the lower part of the abdomen or pelvis, and lumbosacral backache was a frequent complaint. King found abdominal pain in 63 per cent of his patients, and almost without exception exaggeration occurred at the time of menstruation.

Dyspareunia.—Our cases have not been analyzed from the standpoint of dyspareunia, but this complaint has been frequent. Donald reports dyspareunia in 57 per cent of 40 cases and King in 8 per cent of the patients who were questioned in this regard.

Always painful	11.2
No menstrual pain	39.6
Acquired or increasing dysmenorrhea	49.1

DIAGNOSIS

The subjective symptoms of intraperitoneal endometriosis show wide variations in degree as well as in kind. They are dependent on several factors, chief among which are the extent of the lesion, particularly invasion of adjacent structures, and the nature of the complicating pathologic changes. Exaggeration of pain or its occurrence only at the time of or shortly before menstruation is characteristic; but this sequence of events may be absent in a large percentage of cases. The clinical picture as a whole rather than isolated symptoms points to the correct diagnosis. Such a symptom complex may be summarized as follows: (1) age, between 25 and the menopause; (2) sterility, absolute or relative; (3) abnormal menstruation, usually menorrhagia; (4) dysmenorrhea of the acquired type; (5) dyspareunia; (6) sacral backache; (7) intermenstrual lower abdominal pain with increased discomfort at the time of menstruation; (8) pain in the rectum or bladder which bears a distinct relationship to menstruation.

Table 7.—*Symptoms as Reported by Several Authors*

Author	Sterility	Acquired Dysmenorrhea	Menstrual Disturbances	Frequency of Myoma
Donald	40%	50%	Ascribed to associated lesions	55.4% 22.0%
King	"Common occurrence"	"Over 50%"	Usually due to associated lesions	
Smith	20.6%	60.5%	None characteristic	41.6%
Shirer	84 2%	"Practically all"	None characteristic	
Keene and Kimbrough; present series	40.9%	49.1%	None characteristic	Not stated 55.4%

Objective observations likewise vary with the extent and nature of the lesion, but in the presence of ovarian endometriomas, well developed peritoneal implants, or, more commonly, a combination of the two, the observations are fairly uniform and characteristic. On one or both sides of and blending into the partially fixed uterus is a tender, densely adherent, semisolid or firm adnexal mass. Commonly the uterus is in adherent retroflexion or contains one myoma or more. Typical of the lesion are nodulations in the culdesac which are more readily detected by rectal palpation. In our experience, the rectal mucosa overlying the nodulations has invariably been normal in appearance and never adherent to them, an important diagnostic point in differentiating from a malignant growth. Peritoneal implants in the culdesac without gross ovarian lesions give evidence of their presence by an indefinite sense of thickening, by resistance or by nodulation combined with the uterine symptoms already mentioned.

Symptoms referable to the bladder or rectum should be investigated by appropriate methods of examination. The proctoscopic demonstration of a normal rectal mucosa is of diagnostic value. In two of our patients, cystoscopic examination revealed the nature of the pelvic lesion. At the base of the bladder, small vesicles were seen in the center of an intensely reddened and thickened area of mucosa. A few of these vesicles presented a distinctly blue discoloration simulating miniature blue dome cysts of the breast.

Rectovaginal Endometriosis.—Invasion of the rectovaginal septum may exist as an independent lesion, but more commonly it is found in association with similar involvement of the ovary. The small isolated growth may run a symptomless course, but with increase in size and depth of invasion the rectum is encroached on, and pain results which is coincident with menstruation and is relieved during the intermenstrual period. In the six cases that have come under our observation, bleeding from the vagina or rectum has not been present, but this may occur and, as with pain, coincides with the menstrual epoch. The involvement may be so extensive as partially or completely to occlude the rectum or the terminal segment of the ureter, giving rise to symptoms indicative of such an obstruction.

Endometriosis of the Umbilicus and Laparotomy Scars.—Two of our patients presented typical endometriomas of the umbilicus. In one there was an extensive similar involvement of both ovaries and the culdesac. Of interest is the fact that there was no evidence of transplants in the peritoneum of the anterior abdominal wall. In the second case of umbilical involvement, operation showed the pelvic organs to be normal.

Endometriosis of a laparotomy scar was present in one patient, having developed two years subsequent to ventrifixation. The invasion affected the entire thickness of the abdominal wall, forming a tumor 5 by 5 cm. in diameter, and pain, swelling, and discharge of blood accompanied each menstrual period. Primary adenomas of the umbilicus, implantation growth in laparotomy scars and adenomas in the groin present similar clinical pictures, the characteristic symptoms common to all being pain and swelling during the menstrual periods. More rarely there is a periodic discharge of blood from these nodules which is coincident with menstruation. The implantation adenomas are usually attached to the fascia; therefore, during the earlier stages of development they are deeply placed and are recognized as tender, somewhat fixed masses along the laparotomy scar which, on palpation, closely simulate an incarcerated omental hernia. The more superficial growths, or those primarily of umbilical origin, may present a bluish discoloration and give the appearance of a chronic inflammatory thickening.

The periodic discharge of blood from the umbilicus of a patient who has had no previous operation is pathognomonic of an adenoma of the endometrial type. As a postoperative manifestation, on the other hand, such a deduction is not warranted, particularly in the presence of a sinus unassociated with definite nodulation. A true fistula may exist in the tract leading to some structure in the pelvis such as the uterus, ovary or tube which is the source of the bleeding. From the standpoint of appropriate surgical treatment, the differentiation between the bleeding of a superficially placed adenoma and that of an intraperitoneal organ is of paramount importance.

Three of our patients presented a menstruating sinus of the abdominal wall, two of these following cesarean section and one following an operation, the nature of which is unknown. One of these healed spontaneously following the discharge of a silk ligature. The other two patients were operated on; in one the internal opening was the uterine cavity, and in the other it was the outer end of the right fallopian tube.

As an aid in demonstrating the depth and, possibly, the internal opening of the tract, we would suggest a roentgenogram of the fistula and uterus after injection with iodized oil. At the time of operation we have found the injection of an aqueous solution of methylene blue (methylthionine chloride U. S. P.) a valuable aid in visualizing the course and origin of the fistulous tract.

TREATMENT

Ovarian function is essential to the activity and proliferation of all lesions included under endometriosis. Conversely, cessation of activity and progressive atrophy follow ablation of this function. Exceptions to this sequence of events are rarely encountered. Hence the principles of treatment must be based primarily on these established facts, whether in the form of surgical intervention or of irradiation. Being essentially a disease of comparatively young women in whom ovarian conservation is desirable, the decision as to proper treatment may be a perplexing problem.

Only too often radical measures must be adopted, but we are convinced that, whenever possible, it is wiser to err on the side of conservatism. We believe the following results of conservative measures warrant this conclusion: In forty-eight patients, one or both ovaries were conserved and only two have had subsequent pelvic disease; one developed a retention cyst of the conserved ovary a year later, and in the other a symptomless implant was discovered in the vaginal vault six months after operation. In twenty-one patients whose menstrual function was preserved, slight irregularity in bleeding occurred but once. Of fourteen married women in whom the child-bearing function was preserved and who were operated on a year or more ago, normal pregnancy has occurred in 28 per cent.

Table 8.—*Treatment of 109 Ovarian Cases*

	Number
Hysterectomy and bilateral salpingo-oophorectomy	58
Bilateral salpingo-oophorectomy	2
Unilateral oophorectomy and hysterectomy	19
Unilateral oophorectomy	13
Resection of cysts	8
Unilateral oophorectomy and resection of cyst of opposite ovary	4
Unilateral oophorectomy and cauterization of opposite ovary	2
Unilateral oophorectomy, cauterization of opposite ovary and hysterectomy	1
Exploratory laparotomy	1
No operation (young women with mild symptoms)	1

Into the group amenable to conservative measures fall the smaller ovarian adenomas that can be readily excised and the minute superficial implants that are easily destroyed by cauterization. The peritoneal implants are small, symptomless and increase slowly in size. Hence no treatment is necessary.

Unfortunately, radical procedures are required in many cases. Large ovarian endometriomas are invariably densely adherent, so that their liberation is attended by such injury to the ovary, uterus or both that excision of the affected organ is imperative. The ovaries may present only minor lesions or, more rarely, may be normal, yet extensive endometrial invasion of the rectum, sigmoid or bladder has produced decided impairment of their function. Here, again, nothing short of a bilateral oophorectomy will suffice. In the presence of such invasion, excision of the diseased area is rarely necessary. Incident to cessation of ovarian function a gradual regression occurs; this is a slow process, which often requires months for its completion. Advantage should be taken of this atrophic process in the treatment of intestinal obstruction secondary to adenomatous invasion. If the obstruction is complete, it is wise to combine temporary colostomy with bilateral oophorectomy. Should the patient's condition be such that the combined operation is hazardous, the obstruction should be relieved by a colostomy with subsequent oophorectomy or irradiation, depending on the extent and nature of the pelvic condition.

Table 9.—*Types of Treatment of Rectovaginal Septum and Umbilical Endometrioma*

Umbilical cases	2
Excision of umbilicus only*	1
Excision of umbilicus combined with hysterectomy and bilateral salpingo-oophorectomy †	1

* Pelvic organs were normal.
† Both ovaries were extensively involved.

Four patients in our series presented symptoms of chronic, partial intestinal obstruction due to endometrial invasion of the rectum or sigmoid. In one, the lesion was mistaken for carcinoma and resection was performed, while in three, complete relief followed bilateral oophorectomy. A similar result after ovarian excision was obtained in a case of invasion of the bladder, while in a second similar case the endometrial invasion of the bladder regressed but a carcinoma developed subsequently. It is noteworthy that the carcinoma originated from the bladder mucosa and not from the endometrial nodules.[5]

Sixty of our patients with ovarian lesions were treated by operations including total ovarian ablation, while in forty-eight, one or both ovaries were conserved. One mortality occurred in the radically treated group but the remaining 98.3 per cent of these patients have had no evidence of recurrence. Of the group in which ovarian function was conserved, 95.8 per cent were entirely relieved by the operation and the remaining 4.2 per cent were greatly improved.

Read and Roques [6] reported a cure in 71.4 per cent of thirteen patients treated conservatively and in 77 per cent of those in whom both ovaries were removed. Smith found the conservative operation entirely successful in 67.5 per cent and the radical in 100 per cent.

Recurrence of symptoms may follow conservative measures but the lesion is of slow growth and the advantages of continued menstruation as well as the possibility of subsequent childbirth offset the relatively slight risk of such recurrence.

Surgery is the procedure of choice in the treatment of symptomatic intraperitoneal lesions, and irradiation, whether by radium or the x-rays, should be resorted to only in rare instances. Large ovarian endometriomas with their grumous content, dense adhesions and the uterine disease that is commonly present certainly belong in the surgical domain. Conservation of ovarian and uterine function should be the aim whenever feasible and this can be accomplished often by surgery and never by irradiation, since a menopausal dose is required if regression is to follow.

---

[5] Heaney, N. S.: Tr. Am. Gynec. Soc., 1926.
[6] Read, C. D., and Roques, F.: Proc. Roy. Soc. Med., Sect. Obst. & Gynec. 22: 1441, 1929.

Isolated nodules in the rectovaginal septum or an easily accessible area of multiple nodulations may be excised. When the septal invasion is more extensive and is associated with gross ovarian or uterine lesions, or both, we prefer a bilateral oophorectomy and hysterectomy, feeling assured that we can anticipate with certainty a gradual regression of the septal lesion. Often the nodules are situated just behind the cervix, which is fixed in a high position, making excision a difficult as well as hazardous procedure. Unless symptoms directly referable to the lesion are present, we see no indication for excision or any other form of treatment, merely keeping the patient under observation. At present, three such cases are under our care, and as yet there has been no indication for treatment. Should doubt exist as to the exact nature of the growth, biopsy is indicated.

Rectovaginal adenomas which are not associated with demonstrable ovarian lesions and which are producing severe rectal pain, bleeding, backache or partial occlusion can be successfully treated by radium or the x-rays, but the desired results require a menopausal dose. We have used roentgen irradiation in three patients with relief from pain and gradual atrophy of the growth in each case; under such circumstances irradiation is employed for its effect on ovarian function and not with the idea of directly affecting the adenomatous growth. We have had no experience with direct radium implantation, but the treatment does not seem logical and the production of a rectovaginal fistula is certainly not a remote possibility.

Wide excision is the only treatment applicable to primary endometriosis of the umbilicus as well as secondary transplants in the groin and laparotomy scars. A postoperative sinus which discharges blood at the time of menstruation should be carefully investigated to determine whether it is a superficial sinus or a true fistula leading to an intraperitoneal organ. In the latter case, complete excision of the fistulous tract and appropriate surgical treatment of the involved organ are essential to cure.

133 South Thirty-Sixth Street—1907 Spruce Street.

ABSTRACT OF DISCUSSION

Dr. Thomas S. Cullen, *Baltimore:* The subject of endometriosis or adenomyoma has been of especial interest to me for more than thirty years. As has been pointed out today, there is no doubt that the diagnosis of adenomyoma of the uterus can be made in a large number of cases. It is perfectly true that in these cases there is normal endometrium, but there are little rivers of mucosa running all through the diffuse myoma of the uterus, and at the menstrual period there is a tremendous amount of increased tension giving rise to grinding-like and severe pain. At the period, in addition to the blood from the endometrium, blood comes from all the tributaries scattered throughout the uterine walls. In the majority of these cases of adenomyoma there is also a definite tendency toward individual myomatous nodules, which may be very small. Quite frequently there are adhesions. Naturally, in these cases the treatment is supravaginal hysterectomy. As has been mentioned, conservatism is important in those cases in which the endometrial nodules occupy small areas in the ovary. Often, when the process is an early one, portions of both ovaries can be saved. A valuable point in the technic of ovarian suture is the use of very small needles and of delicate catgut. I have found that equally important is the use of a continuous suture. Often only one continuous suture is necessary and only one knot instead of a series of knots. I have had quite a number of cases of adenomyoma of the umbilicus. This is a rare condition, and in the majority of these cases a diagnosis can be made from the little reddening of the umbilicus at the menstrual period, and sometimes there is an escape of blood from the navel at this time. The question of adenomyoma or endometriosis of the round ligament has interested me considerably, because the first case on record came from our operating room, about 1896. When there is a nodule directly back of the cervix—very small and with no induration on either side—one can say with almost absolute certainty that adenomyoma of the rectovaginal septum exists. Sometimes, as the process progresses, there is an extension laterally with involvement of the ureters. In such cases there is pain in one or both kidney regions at the period. I have seen the process so extensive that the ureters literally had to be tunneled out of the adenomyomatous tissue and lifted up and sutured along the side of the pelvic wall to avoid subsequent constriction.

NARCOSIS AS THERAPY IN NEUROPSYCHIATRIC CONDITIONS*

W. J. BLECKWENN, M.D.
Associate Professor of Neuropsychiatry, University of Wisconsin Medical School
MADISON, WIS.

By narcosis I mean a state of deep sleep or unconsciousness, more or less prolonged, and quite rapidly induced by means of drugs; a condition similar to the state of general anesthesia necessary for surgical operation, but not as profound.

There is reported herewith the effect of narcosis in certain mental states, and its use as a therapeutic measure in the clinical management of various neuropsychiatric conditions.

Before taking up the conditions in which deep sleep has been a decidedly beneficial therapy, I wish to emphasize, what seems quite unnecessary, the essential need of sleep in man and animal as well. Sleep is a biologic reaction of defense on the part of the animal organism against fatigue. Any disturbance of this natural cycle is attended with grave results. The continuous loss of sleep over a period of from five to seven days is incompatible with life. In all probability, the phase of sleep in the normal cycle represents a period of cellular rest, during which time the metabolic processes are directed toward building up a storehouse of energy for subsequent expenditure. Without such a phase in the life cycle of a cell, exhaustion and even death occurs. In short, sleep is essential to maintain life.

Disordered sleep is a common manifestation of nervous disorders. In certain psychoses and states of mental excitement the absence of sleep adds to the gravity of the situation. With all these things in mind, we, at the University of Wisconsin, have been particularly interested in such measures as would bring about periods of sleep without subsequent depression. We have sought for means of inducing states of mental and physical relaxation such as are observed in normal sleep, hoping thereby to favor the natural restorative processes.

---

* Read before the Section on Nervous and Mental Diseases at the Eighty-First Annual Session of the American Medical Association, Detroit, June 26, 1930.

We have felt urged to meet in a more positive and helpful way some of the difficult situations that so frequently present themselves to the neuropsychiatrist. These are the violently disturbed cases, especially the extreme instances of continued psychomotor unrest observed in the manic, catatonic excitement, and the agitated depression of the involutional period; those cases in which the commonly used hypnotics are ineffectual, and in which hydrotherapy usually becomes a means of mere mechanical restraint. And, finally, we hope to prevent, if possible, what so frequently happens in these cases of great excitement, the rapid physical decline and exhaustion with terminal pneumonia or death from cardiac failure.

Following our earlier experience in the use of narcosis in these clinically serious cases, we began to apply these principles to the milder cases in which disordered sleep was essentially the distressing symptom, particularly those cases associated with the psychoneuroses. Further, we have used our method in the convulsive states—especially status epilepticus, eclampsia and tetanus. The other conditions treated will be mentioned later.

Anhydrous sodium iso-amylethyl barbiturate is a white crystalline substance which decomposes rapidly if allowed to stand in solution. Page and Coryllos[1] prepared this sodium salt and were the first to use the drug as an anesthetic in dogs. Zerfas, McCallum and their associates[2] reported the first work in the field of surgical anesthesia in man. I[3] have made previous reports on the use of this drug in the treatment of the psychoses.

Practically all of the work with sodium iso-amylethyl barbiturate has been done with the aim of bringing about a state of surgical anesthesia. I wish to emphasize the point that in our efforts we have a different objective. We are not concerned with the production of a state of deep surgical anesthesia. Instead we are seeking to produce a phase of unconsciousness which is possibly a trifle deeper, in its initial stage, than normal sleep.

For this reason the technic I will advocate is quite different from that used by the surgical anesthetist. Incidentally, when this technic is carefully followed, none of the occasionally distressing reactions will be encountered.

Before discussing the manner in which we advocate the use of this drug in neuropsychiatric conditions, I will briefly mention the clinical types that we have thus far treated beneficially by the use of periodic narcosis.

THE PSYCHOSES

The manic phase of manic-depressive psychosis has been successfully precipitated into profound and prolonged sleep at will. The initial struggle in making the injection is negligible. The course of the illness has been decidely abbreviated by a regular series of deep sleeps.

It is our practice to produce the narcosis once in twenty-four hours. While this initial phase of deep sleep lasts from four to eight hours on the average, there follows a period of four to six hours during which time the formerly excited and restless patient remains awake but is quieter and more relaxed. Not infrequently a period of natural sleep now follows. If narcosis is produced daily, the patients rarely reach the peak of mental or physical unrest manifest before the drug was employed.

We have also treated a number of depressed patients. In these the favorable response took the form of more prompt compliance with requests and a greater willingness to accept food. They became more active, more interested in their surroundings and one found a freedom from the awkward, constrained postures usually seen in this type. The depression is certainly less profound and the course of the illness is materially shortened, with the use of the drug.

The agitated depressions of the involutional type are treated quite like the excited states. The results are, if anything, more striking. A sufficient number of patients have made complete recoveries in from ten to fourteen days to eliminate the probability of chance. In other words, in cases which would normally be expected to continue for from six months to a year, recoveries have occurred in two to three weeks.

SCHIZOPHRENIA

The catatonic patient has shown some extremely interesting and rather striking responses. Several cases of catatonic excitement have been treated with excellent results. The following case is cited as an example:

J. L., age 20, a university student, while attending classes developed a sudden onset of confusion and mutism. After three weeks of negativism with a refusal to eat food, followed by a state of marked excitement, he developed active hallucinations, made bizarre gesticulations and facial grimaces, and became noisy, singing and yelling day and night. He was given sodium iso-amylethyl barbiturate and just as he was going to sleep said that he realized he was having a terrible time and hoped to recover so as to enter school at the beginning of the next semester. After his initial sleep he seemed quite normal for about four hours, during which time he discussed current topics, his illness, school and his future plans. He then fell asleep spontaneously, and on awakening from his second sleep he returned to his excited state. Daily injections for about three weeks produced similar results, except that his periods of being normal increased as the excitement gradually subsided. He was transferred to a sanatorium, where he continued to improve. During his stay there he became interested in outdoor activities and decided to follow an outdoor life and not to return to school. He has been successfully employed with a florist for six months and seems perfectly adjusted at present.

A series of some twenty cases of catatonia of the stuporous, cataleptic and negativistic types have been treated. With a few exceptions some extremely interesting and unusual reactions have occurred. These have been reported in previous communications.[4]

Periods of from four to fourteen hours of a "normal lucid interval" have been a constant result of the treatment, and during these intervals nourishment is taken voluntarily and often requested, whereas they were necessarily fed through a tube when the drug was not used.

PSYCHONEUROSIS

Some of the more severe psychoneuroses with distressing insomnia were speedily relieved. As soon as a periodic cycle of sleep was established, these patients began to improve. They had a better appetite, gained weight, had fewer neurasthenic complaints, were more optimistic. The entire picture changed. After several weeks of induction of sleep the drug was discontinued and it was unnecessary to use the drug subsequently.

[4] Bleckwenn (footnote 3). Lorenz, W. F.: Some Observations in Catatonia, Psychiatric Quart. 4:95 (Jan.) 1930.

In these cases we have found that psychotherapy in the form of persuasion and suggestion become much more effective when combined with this periodic induction of sleep.

In several of these cases the use of various drugs over a period of years virtually amounted to true drug addiction. After sleep had been periodically induced, it was found that these patients no longer required the sedative drugs previously used.

CONVULSIVE STATES

In status epilepticus this drug is of real value. In two cases it was a life saving measure. In a third case it permitted an epileptic woman to go to full term in her pregnancy.

A boy, aged 14, developed jacksonian convulsions. Following this focal type of seizure, a status epilepticus of four hours' duration ensued. Morphine, chloral hydrate and ether inhalations were ineffective. At the end of four hours his temperature was 105 F. and his pulse 180. He showed irregular breathing, cyanosis and pulmonary edema. He appeared to be at the point of death. Sodium iso-amylethyl barbiturate was administered intravenously and the convulsions ceased during the injection. After six hours they reappeared and a second smaller dose was administered; following this the boy recovered from his convulsions. An infiltrating glioma of the frontal lobe was found at operation.

Several cases of eclampsia and two cases of tetanus with convulsions also responded with a cessation of the convulsions as the result of intravenous use of this drug.

METHOD AND DOSAGE

For therapeutic purposes in the types mentioned, a certain method and technic of administration is essential.

This consists of (1) dosage; (2) dilution of drug; (3) rate of intravenous injection; (4) depth of narcosis.

The following technic has been successful in our hands:

The patient should have no food for from four to six hours preceding drug administration.

The drug is freshly dissolved in triple distilled water. A 5 per cent solution is made. Each cubic centimeter thus contains three-fourths grain of the drug. The original dilution of Zerfas and his associates [2] is therefore changed. They advocate a 10 per cent solution, or 1½ grains per cubic centimeter.

The drug is injected intravenously at a rate not to exceed 1 cc. per minute. It is necessary to use a watch for this, since it is extremely difficult to inject accurately from 10 to 20 cc. over a period of from ten to twenty minutes without the hesitating, jerky type of injection.

The initial dosage is individual and for neuropsychiatric cases it is absolutely safe to give 2 cc. (1½ grains) more than is necessary to produce corneal anesthesia. We use the abolition of the corneal reflex as our criterion of proper narcosis and give an additional 1½ grains.

The average neuropsychiatric patient will thus receive between 7 and 15 grains intravenously. This is approximately half the amount used for surgical anesthesia.

In only one case have we found it necessary to exceed 15 grains in order to produce the required narcosis. This was in a woman who had received more than 250 injections during a period of nine months. It gradually became necessary to increase the dose to 21 grains. There seems to be a slight increase in the tolerance for the drug after prolonged use.

The drug may be used intramuscularly, in which event the dosage is increased and the solution is more concentrated.

A 20 per cent solution is prepared, and of this we give from 2.5 to 5 cc. or from 10 to 20 grains.

By the intramuscular route a narcosis is produced, but this is slower in its development and less profound, as compared with the response to the intravenous method.

In mild cases the drug can be used orally in doses of from 3 to 6 grains. It takes about forty-five minutes to be effective. It is effective as a hypnotic in the less severe types and is ineffective in the disturbed and violent cases.

And, finally, the patient must always be watched by a nurse from the time of administration of the drug until the initial narcosis wears off. This precaution is advisable because of the dangers of aspiration of vomitus and, further, because of the depth of narcosis and possibilities of suffocation.

As previously reported,[3] we advise caution in the use of iso-amylethyl barbiturate in cases of advanced arteriosclerosis.

If our method of administration is followed, observing the factor of greater dilution and measured rate of injection, the occasionally embarrassing reactions of greatly lowered blood pressure and shallow respiration are avoided.

Our experience with this drug now covers a period of more than a year. During this time more than 2,000 injections have been made in 184 cases. We are greatly impressed with the fact that the drug can be used daily over long periods of time without any untoward reactions.

CONCLUSIONS

1. Sodium iso-amylethyl barbiturate used according to the method advocated will induce narcosis in the various types of excitement and benign depression and in the convulsive states.
2. Periodically induced narcosis is decidedly beneficial in these cases, simplifying the management and materially shortening the course of the illness.
3. Normal lucid intervals, with spontaneous speech and the taking of nourishment, are seen in protracted cases of catatonic schizophrenia.
4. Periodic narcosis breaks down the stubborn insomnia associated with the more severe psychoneurosis.

ABSTRACT OF DISCUSSION

Dr. Harry Stack Sullivan, Towson, Md.: I would counsel, first, a measured optimism as to drug therapy in schizophrenia. I have not used preparations of iso-amylethyl barbituric acid but I have had some experience which is collateral to Dr. Bleckwenn's presentation. Some years ago it occurred to me that the impasse in which schizophrenic patients quite frequently come to rest indicated the use of pharmacodynamic agents that disturb the conscious processes. Dr. Ernest Hadley undertook to investigate the utility of atropine. This drug entailed so great a disturbance of the physiology of the patient that it was used in but three cases. Each of these, after an atropine delirium, showed a marked change of state —a marked and a persistent change, something of psychologic importance rather than merely transient phenomena. The disturbances of vegetative enervation and other complications seem to forbid the continued use of belladonna alkaloids, and we are still searching for the ideal delirifacient. Five years ago there was received into Sheppard Hospital a clergyman, aged 46, in catatonic excitement of such severity as rapidly to progress into dangerous physical collapse. I decided to intoxicate him deeply with ethyl alcohol. His severe intoxication was continued until his mental state had improved to the point at which he became aware of the identity of the therapeutic agent and objected to the treatment. He has been preaching for the last three years, having made an uninterrupted recovery. Since that time I have used this agent in the small percentage of acute and promising patients in whom originally high-velocity processes had subsided into a relatively unchanging detachment from all useful contacts; in other words, where there has appeared a continued useless preoccupation with schizophrenic content. The method has consisted of producing deep alcoholic intoxication and continuing it from six to fourteen days. The method has proved very useful and has been responsible for recovered accessibility in a number of patients who seemed otherwise to be proceeding toward the customary dilapidation. The drug has no curative effects in itself; it is an adjuvant which may be used when indicated by an impasse and it functions to reduce conflict, improve the patient's social contact, and clear the way for psychotherapy.

Dr. Meyer Solomon, Chicago: Drug therapy has been neglected much too often. When the literature of the psychoanalytic school, for instance, is combed, although they are handling anxiety states with insomnias, one never sees any reference to drug therapy as an adjuvant of psychotherapy. Paul Dubois and Dejerine practically advocate that drugs should not be used even for persistent insomnia in psychoneuroses. However, in handling psychoneurotic cases one sees patients who are being exhausted from failure to sleep and rest, which is often really responsible for their failure to eat or for their loss of weight, and I have often wondered what some of the men who are writing purely along psychotherapeutic lines do in these cases. They make no mention of anything other than their psychotherapeutic methods. My personal experience has been that I have been compelled to use hypnotics freely and judiciously in the handling of insomnia in psychoneurotic patients and similar states in psychotic patients. I am sure that what Dr. Bleckwenn has said about the early handling of the fatigue states and insomnia prevents aggravation that otherwise occurs. I have the firm conviction that those who are approaching the problem from a purely psychogenic and psychotherapeutic point of view are missing an opportunity if they fail to resort to pharmacotherapy that is really needed. If a patient can be made to have two or three weeks of good, sound sleep he is much more amenable to explanation, to discussion, to analysis of the psychogenic factors. In the early phase, with a fatigued patient, to begin to endeavor to unearth psychogenic factors only without handling his outstanding symptoms is an error. The fundamental object should be to relieve the symptoms; and, in addition to etiologic psychotherapy in psychogenic cases, relief of insomnia is a fundamental therapeutic object.

Dr. Albert E. Sterne, Indianapolis: I commend the author's position absolutely, not only for the views expressed, but because I can corroborate the results of the therapy he uses. I have had the opportunity of using sodium iso-amylethyl for a long time in excited cases of all kinds and descriptions. I have not limited myself to any one particular class. I have even used it in the extreme excitement of alcoholism with excellent results. I use the sodium iso-amylethyl intravenously and in exactly the same way, with especial emphasis on the slowness of injection. It must be given carefully and with some regard to the weight, and other elements in the equation, of that particular patient. In the last few years I have shifted the technic. I do not use it so much intravenously as I did. I use it by rectum, with similar results. I have kept a number of patients constantly semianesthetized for from five days to ten days, feeding them all this time especially fluids, if necessary in some instances with the nasal tube. I have kept them under most of the time, drowned them out some of the time, with the result that they have come out of the period of excitement and agitation, and conditions similar to that, have become tranquil, and have gone on to an almost uninterrupted recovery. After an experience of close to forty years, I must say that I have found nothing in the Pharmacopeia that has given anything like the results in drug usage that I have found in either the intravenous or the rectal use of sodium iso-amylethyl. I am at present also using it by mouth. Naturally, all the rest of the phases of the patient's treatment must be kept in the foreground; the baths must be given and the care of the patient kept constant during the period of semianesthesia, or seminarcosis.

Dr. George A. Moleen, Denver: I think that if every one agreed on subjects it would suggest the same provincial locality. It seems impossible to agree on the therapeutics which has as its purpose the achievement which form the most essential part of Dr. Bleckween's presentation; namely, the induction of sleep. The value of sleep, all will agree on, but I am not so convinced that any of the barbituric acid series are so free from later effects. I took occasion in New Orleans to raise that point when the late Dr. Grinker spoke of phenobarbital in connection with epilepsy, in that all, whether the methyl or the ethyl, derivatives of barbituric acid were open to question. The fundamental fact was that they may be retained in the blood as nitrogenous poisons, and in cases in which the elimination was defective—in which there was a renal inhibition—they were bound to have some ulterior effect. I had occasion to see a case of insomnia which was mentioned in the discussion to which I referred, in which either barbital or iso-amylethyl barbituric acid was given in order to bring about quiet toward evening. It was given in repeated doses until this was established, and a uremic delirium was induced which was pronounced, and fatal in the end. That was only one case but I feel sure there have been many of the same general nature. I believe it was von Leube who long ago suggested the importance of narcosis in excitable states, such as agitated melancholia, when he used opium in the form of tincture of opium and also chloral and bromides—combinations of them—to produce the same effect. The only point I want to make now, however, is that the barbaturic acid series, which is so popular now in the induction of quiet and sedative reactions, is not so free from danger as so many assert.

Dr. W. J. Bleckwenn, Madison, Wis.: I fully subscribe to the thought that barbiturates may be dangerous. However, with the technic such as I have outlined, no difficulties have been encountered. One patient has received 250 daily injections of from 15 to 22 grains (1 to 1.4 Gm.) of sodium iso-amylethyl barbiturate over a period of nine months. Throughout this period, careful clinical studies have been made, as well as biweekly laboratory check-ups consisting of kidney and liver function tests, and chemical examinations of the blood and the urine. There has been no disturbance seen over this long period. I fully appreciate Dr. Sterne's remarks. I did not know some one was here who had had such a long experience with this drug. I cannot, however, subscribe to the suggestion of continuous prolonged narcosis. This, of course, has been practiced for a long time. The point I tried to make in this paper and which I repeat for emphasis is that the periodic induction of sleep in each twenty-four hours should be one's therapeutic effort. This follows closely what is seen in the normal. This cyclic sleep permits of the cellular restoration of function and in my experience produces more rapid recoveries.

Nervous Breakdowns.—Given an inheritance of poor nervous tissue, a breakdown can come at any time and often without apparent cause. We see this in the lives of Wedgwood and Darwin and Galatin; they were all independently wealthy; they never had to work for a living; they were surrounded by devoted relatives, and yet they went to pieces nervously. It should be remembered also that Darwin broke down after years of outdoor life as an explorer and naturalist; one would think that such a life should have given him an iron constitution, but it did not. In many cases the nervous system seems to be made of poor materials, and like a defective tire, it blows out after a thousand miles instead of after the guaranteed ten thousand. In other cases, especially when the break comes in the latter half of life, I often suspect that it follows a slight unrecognized "stroke"; that is, some vascular injury to one or more small areas in the brain. In other cases there may perhaps have been a slight encephalitis, not severe enough to produce definite sleeping sickness with a masklike face, but enough to leave the brain crippled for months or years.—Alvarez, W. C.: Nervous Indigestion, New York, Paul B. Hoeber, Inc.

ABDOMINOPERINEAL OPERATION FOR CANCER OF THE RECTUM *

T. E. JONES, M.D.
CLEVELAND

A review of the history of cases of cancer of the rectum shows that there is still neglect of digital or proctoscopic examination of patients who present themselves for relief of bleeding from the rectum. Occasionally a patient does not seek medical advice until he is in a hopeless condition, but in this series of cases it was found that, while most of the patients did consult a physician from three to six months previously for the relief of rectal bleeding, the physician was misled by coexisting hemorrhoids and advised only palliative treatment. As a result, the patient left with a false sense of security and did not again seek relief for several weeks or months. That this is true is well borne out by the statistics, which show that in the past four years, from among 185 cases of cancer of the rectum seen at the Cleveland Clinic, 70 cases were hopelessly inoperable on account of the extent of the local disease or because of metastases. In our series of cases, the average duration of symptoms—constipation and bleeding from the rectum—was eight months; 25 cases had been seen previously without investigation having been made. Too often this is the case. The plea today—as it always has been—is for digital and proctoscopic examination in all cases of rectal bleeding, whether or not hemorrhoids are readily seen on inspection.

The decision as to whether a case of cancer of the rectum is operable varies with the surgeon. Operability is variously estimated at from 20 to 80 per cent of the total number of cases presented to the surgeon according to the extent of the operation and the criterion of the surgeon as to what constitutes operability. Naturally, the lower the percentage of operability, the greater the percentage of cures, and vice versa. If the surgeon considers only 30 per cent of his cases to be operable, it is reasonable to suppose that his percentage of cures will be greater than that of the surgeon who operates on 60 per cent of his patients. In the desire to secure a high percentage of cures, the surgeon sometimes loses sight of his duty to the patient—that is, to make him comfortable for a time if possible. It is also well known that in general the higher the percentage of operability the higher the mortality from operation, because the surgeon takes greater risks in the hope of accomplishing a cure. It would seem that he is justified in doing this. Of the 185 cases in our series, 60 per cent were operable, but in 15 per cent, or 28 of these cases, the patients refused operative treatment, some of them returning later in a hopeless condition.

In a case of cancer of the rectum, if removal of the rectum is contemplated, a thorough knowledge of the lymphatic drainage is essential. Miles's contribution along this line has been outstanding and has been referred to in a previous paper.[1] Three groups of glands must be removed—first, those in the ischiorectal space; second, the glands along the levator ani muscles; and, third, the glands in the mesosigmoid which accompany the inferior hemorrhoidal vessels. It is our opinion that the removal of these glands can be best accomplished by the one stage abdominoperineal operation so lucidly described by Miles.

After the diagnosis has been made, the patient is hospitalized and preoperative therapy is begun. This preoperative therapy is essential to the success of the operation. Practically all of these patients have more or less obstruction and it takes many days to empty the bowels. This is accomplished by giving the patient daily 1 ounce (30 Gm.) of magnesium sulphate in 6 ounces (175 cc.) of water—a tablespoonful of the mixture every half hour. This method prevents a drastic cathartic effect. In addition, cleansing enemas are given daily. The foregoing procedure is repeated for several days and it is amazing to see the change in the contour of the abdomen. *Bacillus acidophilus*, which helps to change the flora of the large intestine, is of benefit. All laxatives are discontinued on the day previous to operation.

The patient is put on a nonresidue diet consisting chiefly of large amounts of orange juice and sugar in the form of hard candy and, since it is believed that some of the unexplained deaths are due to liver failure, intravenous injections of dextrose are given daily to build up the glycogen content of the liver. Many patients, on account of intestinal disturbance, have had a poor appetite for weeks, and they must be built up. During their hospital stay, chemical examinations of the blood are made and the kidney function is thoroughly investigated. Digitalis is given frequently. A blood transfusion is given either before or after operation, according to the condition of the patient. Preoperative therapy should occupy from seven to ten days.

Spinal anesthesia is the preferable method. By any other method the operation would be much more difficult, and in some cases, especially on obese patients, it would be impossible. Absolute relaxation is imperative and this is secured by spinal anesthesia. For the past two years in the Cleveland Clinic we have been using a proprietary mixture of procaine hydrochloride and strychnine. In about one out of ten of our early cases this solution produced only an incomplete anesthesia. Finally we changed our technic from that originally outlined by Pitkin and since then we have not had a single failure. After the introduction of the anesthetic the patient is placed on his abdomen instead of on his back, because the solution, being lighter than the spinal fluid by this maneuver is more likely to come in contact with the sensory roots, which are the posterior roots. When the anesthesia has reached the costal border, the patient is again turned on his back and placed in the Trendelenburg position at an angle of 10 degrees.

An adequate midline or rectus incision is made and the liver and abdomen are explored for metastasis. If the case is pronounced operable, the intestines are packed off with gauze. If the sigmoid is adherent, it is mobilized by dividing the peritoneal attachment on the lateral side. The inferior mesenteric artery is then located about 1 inch (2.5 cm.) below the bifurcation of the aorta and is ligated below the first sigmoid branch. The peritoneum is then divided on either side of the sigmoid down to the promontory of the sacrum, thus bringing into view the cellular space between the anterior surface of the sacrum and the pelvic mesocolon. The hand is placed within this space and the fat is separated as far as the sacrococcygeal articulation. Traction of the bowel will then render prominent the peritoneum of the pelvic floor, which is cut forward on each side as far as the base of the bladder in the male, or as far as the upper part of the vagina in the female.

---

* From the Cleveland Clinic.

* Read before the Section on Surgery, General and Abdominal, at the Eighty-First Annual Session of the American Medical Association, Detroit, June 27, 1930.

[1] Jones, T. E.: Surgical Treatment of Carcinoma of the Rectum, J. A. M. A. **91**: 1711-1713 (Dec. 1) 1928.

In the male, the anterior wall of the rectum is separated from the base of the bladder down to the upper level of the prostate, care being taken not to injure the seminal vesicle or the vas deferens. In the female, the anterior wall of the rectum is separated from the posterior wall of the vagina as far down as possible. After this procedure, the lateral attachments of the rectum are divided as close to the pelvic wall as possible. The next step consists in crushing the bowel in a favorable place for a colostomy without too long a loop, and dividing it with a cautery. In our early cases we invaginated the ends of the bowel, but now we use the Miles procedure, and after tying the bowel we cover it over with a square piece of rubber dam. This saves time and avoids danger of contamination. The distal end of the bowel is then pushed down into the pelvis and the peritoneum is closed over it, care being taken not to cause kinking of the terminal ileum. If there is not a sufficient amount of available peritoneum, a flap may be dissected from the base of the bladder in the male or from the broad ligaments in the female, or an omental graft may be placed directly over the open space. If necessary, the fundus of the uterus can be stitched to the peritoneum at the promontory of the sacrum.

A left McBurney incision is made and the proximal end of the colon is brought out through the incision. The abdominal incision is then closed up and the patient is placed on his abdomen with the hips slightly elevated. The perineal part of the operation is begun by putting a purse string suture around the anus. A midline incision is then made from the sacrum to the perineum, a considerable portion of the perianal skin is removed, and the flaps are then dissected back to the edge of the gluteus muscle.

After the removal of the coccyx at the sacrococcygeal articulation, we come into the large cavity which contains the distal portion of the bowel, traction on which brings into view the levator ani muscles, which are divided as far laterally as possible in order to remove the glands which are adjacent to them. The rectum is then dissected from the tissues from above downward, the ischiorectal spaces being cleaned out thoroughly.

There now remains a large cavity surrounded only by the bony walls of the pelvis. It is obvious that this cavity cannot be closed and must heal in by granulation. A large square of rubber dam is laid in the cavity and gauze is packed inside to support the pelvic floor and prevent oozing; if gauze alone is used, it becomes adherent to the pelvic floor and is difficult to remove. The packing is removed on the second or third day, according to the condition of the patient, and irrigation with boric acid solution is begun. The colostomy is opened on the first or second day after operation, depending on the degree of discomfort experienced by the patient. If there are no postoperative complications, the patient is encouraged to get on his feet as soon as possible in order to allow the new pelvic floor to stretch and fill up the cavity.

In our series of forty cases of cancer of the rectum in which this operation was performed, there were five deaths, a mortality of 12.5 per cent. In one case, that of a man, aged 71, death was due to acute suppression of urine; autopsy revealed small, sclerotic kidneys. In the case of a woman, aged 61, autopsy showed subacute nephritis and partial obstruction of the lower part of the ileum. In a third case, that of a man, aged 65, autopsy showed paralytic ileus; there was no evidence of peritonitis. In the case of the fourth death, that of a man, aged 53, autopsy revealed obstruction in the terminal ileum due to constriction caused by pulling on the peritoneum in order to make the new pelvic floor. In the fifth case, that of a man, aged 67, autopsy revealed obstruction of a loop of ileum caused by a piece of omentum which was sewed down to cover a small opening in the pelvic floor.

It is apparent that the greatest danger encountered in this operation is obstruction from various causes. However, with the improved technic and the knowledge gained from experience, the mortality in the future should be greatly reduced. In closing over the pelvic floor, rather than to draw the peritoneum too tightly and cause kinking of the lower ileum, it is preferable to cover up any small opening with an omental graft instead of sewing the omentum over the defect, thus causing kinking of the intestines.

As five years has not elapsed since this series was started, it is useless to speak of end-results, but each case is being followed closely. Of the thirty-five patients surviving operation, thirty are living; five are dead. Of these five, three had metastases in the liver and two had local recurrence in the pelvis. The average duration of life in these five cases was fifteen months. Postoperative roentgen therapy was not used in any of these cases.

Forty one-stage abdominoperineal operations for cancer of the rectum are reported, so that after sufficient time has elapsed the result of this operation may be compared with the end-results of less radical operations. It can then be ascertained whether or not the abdominoperineal operation for cancer of the rectum is justified.

Euclid Avenue at Ninety-Third Street.

ABSTRACT OF DISCUSSION

DR. LOUIS J. HIRSCHMAN, Detroit: The abdominoperineal operation is the operation of choice in almost every case of carcinoma of the rectum or rectosigmoid. Conservatism means to conserve life; therefore, conservatism is the utmost radicalism. It is unnecessary to keep a patient in the hospital from seven to ten days in order to empty the colon before a radical operation for carcinoma. In addition to a cathartic, I use a 25 to 30 per cent solution of hydrogen dioxide introduced through a soft rubber catheter passed through the proctoscope so that it goes through the stricture and above; it will disintegrate the hardest type of impaction and empty the colon within three days in any case. More persons die after an operation for carcinoma from intestinal obstruction than any other single cause. Therefore, everything possible should be done to prevent obstruction. The commonest cause of postoperative obstruction is injury or adhesion. Spinal anesthesia gives more relaxation and one does not have to worry so much as formerly about packing off the bowels, which means that one is using force; and gauze, either wet or dry, insults the delicate peritoneal covering of the bowel and invites an agglutination to another portion of the bowel or surrounding tissues. Autopsy has shown that these adhesions occur, and, I think, frequently, as the result of the indiscriminate and forceful "packing away" of the intestines. By using spinal anesthesia and a rubber dam to protect the bowel from the surgeon with his gauze, one has a perfectly clean field in which to work, without postoperative traumatic obstruction from adhesions. For the comfort of the patient afterward I believe that a central placement of the colostomy is desirable. I have been using the umbilicus for that placement. Nature has provided a strong supporting force around an opening into the peritoneum at that point, and the rectus is particularly strong and gives good sphincteric action; moreover, through using that as the central point of the incision, carrying it from there slightly upward and downward, one can explore the liver, the peritoneum, the mesentery and all the other organs for metastasis and can pick out any portion of the colon for the colostomy. Then afterward, if the patient has to wear a pad or even wear one of those "diabolical bags" that Dr. Jones speaks of, it is placed in a central location and he does not have an embarrassing and telltale bulge in his clothing off to one side, and the discharge does not irritate the anterior superior spine. A patient who has had a coccyx removed sits against the edge of the sacrum. The coccyx should not be removed but just bent back and permitted to come into place afterward.

Dr. Curtice Rosser, Dallas, Texas: I agree with Dr. Hirschman that there it no necessity for removing bone. Cancer does not metastasize to the sacrum or to the coccyx, and it is not essential to remove either. The Kraske procedure became so popular that even to this day the term Kraske in the usual operating room is a synonym for any type of perineal resection of cancer. The agreement to sacrifice the sphincters was hard won but is now apparent. The sacral anus was then abandoned with almost as complete unanimity, and the permanent colostomy is now the procedure of universal choice. I am unwilling, however, to see any one procedure, no matter how attractive, adopted for every case of rectal cancer with disregard of the location of the growth, its extent, and the age and condition of the patient. Moreover, Rankin and others have stressed the tremendous importance in many cases of drainage preliminary to any type of colonic resection, and the graded operation has proved its value where even slight obstruction is present. Lockhart-Mummery, in his report of 200 cases of cancer treated by his radical perineal resection (which, of course, is an entirely different procedure from the old Kraske procedure in the amount of tissue it removes), while granting the undoubted need for the abdominoperineal operation for growths high in the rectum or the rectosigmoid, demonstrated that the radical perineal route was practicable with a mortality as low as 3 per cent. His combined mortality was around 8 per cent. Furthermore, he showed that it can be performed in patients over 60 as well as in those in whom obesity makes the abdominal procedure unduly dangerous, and his five-year results show a proportion of cures greater than 50 per cent. It would appear, if I read Dr. Jones's figures correctly, that in approximately 21.5 per cent of the cases seen by him the abdominoperineal operation apparently was justified. In other words, without some other procedure, a large percentage of cases, including those, of course, which were inoperable, would have been without benefit of removal of the growth. The contention of those favoring the perineal procedure in cancers of the anal canal or lower rectum is that the increased operability and lowered primary mortality make it possible to carry a greater number of cases of the total number seen through the five-year period. It is suggested, therefore, that some type of radical perineal resection should be in the surgeon's armamentarium in addition to the procedure described by the author.

Dr. J. Shelton Horsley, Richmond, Va.: The ideal method of treating cancer surgically is to remove it in a block dissection, and this means a one-stage operation. Sometimes shock can to a large extent be obviated by a continuous intravenous injection of dextrose and Ringer's solution. When the sigmoid is to be divided between two clamps, I make the incision for the permanent anus first, and slip a clamp through this incision to grasp the prospective oral end of the bowel. Then a clamp is placed on what will be the distal end, the division is made between these two clamps with the cautery, and the stump is thoroughly cauterized. The upper clamp can then be drawn out with the oral stump and left in place for several days, and when it is removed the anus is in its proper location. Of course, the stump should be fixed with a few sutures. This step saves the infolding and the suturing of the upper end. Shock may occur in the combined operation; and particularly when spinal anesthesia is used in these cases, which is undoubtedly preferable, the continuous intravenous injection of dextrose and Ringer's solution tends to hold up the blood pressure. I have been using this apparatus for the injection for several years. There is nothing original in it except the cannula. After the spinal anesthesia has begun, before the operation is started, this cannula is inserted. In some instances a hypodermic needle is all that will be necessary, but the cannula makes it more certain that the solution will continue. A small flow is begun at once, and as the operation proceeds, when the blood pressure begins to drop because of spinal anesthesia or shock, the flow is turned on full enough to keep the blood pressure reasonably well up, about 10 or 15 points below the patient's normal. Then the flow is reduced. It does not make much difference how rapidly it flows in cases like this; the heart cannot be overstrained when there is lack of fluid in the vascular system, as there is in shock. Matas first used the continuous intravenous injection of dextrose solution. I modified his method slightly by using this buret, for the flow can be regulated quite accurately by this narrow buret, and also by adding Ringer's solution to the dextrose. Ringer found that the addition of calcium causes the contractions of the heart to become stronger. I give a small amount of insulin, not enough for all of the dextrose, but in order to help the weakened patient, who probably cannot excrete quite enough insulin to take care of the excessive amount of dextrose.

Dr. Frank H. Lahey, Boston: In seven cases of cancer of the rectum I have employed an operation (1) for the purpose of securing good drainage by a preliminary colostomy; (2) to remove a segment of rectum that was clean; (3) to divide the magnitude of the operation into a lesser operation first, and a larger operation second, and (4) to establish good drainage posteriorly when the segment was removed. An incision is made from the pubis to the umbilicus. The sigmoid is pulled out up in the abdominal wall. The vessels of the sigmoid are ligated from the bowel down to but not including the superior hemorrhoidal vein and artery. A counterincision is made over the left side of the lower part of the abdomen and a clamp passed through it to grasp the sigmoid at the point where its mesentery is ligated. Another clamp grasps the sigmoid just below this point but in the median incision. The bowel is cut between the clamps with a cautery and the upper end pulled out through the left incision as a colostomy. The lower end of the sigmoid is implanted just above the pubis in the median incision and both leaves of the peritoneum of the cut mesentery are sutured together to prevent adhesions between the first and second stages of the operation, and the abdomen is closed. This represents the first stage of the operation. This, then, represents a segregated lower segment which is irrigated daily for two weeks. Three days before the second stage, the lower segment is irrigated with mercurochrome-220 soluble to make it as clean as possible, so that when the second stage operation is undertaken, from ten to fourteen days after the first stage, the bowel movements are well established, the lower segment has been irrigated clean, and the patient is in excellent condition. The second stage is then undertaken by closing the lower open end of bowel as the anus is closed for the posterior operation. The abdomen is reopened, the parietal peritoneum is cut beside the rectum, the superior hemorrhoidal vessels are ligated and the second stage is then concluded, as would be a preliminary one-stage abdominosacral operation, except that this lower segment is well cleaned, the inflammation about the tumor has gone down from irrigation, sepsis has been taken care of to a considerable extent, and the patient is in good condition because of the previously established colostomy. The patient can then be turned over, a clean segment of bowel removed from behind, after freeing above, and the major portion of the operation done in the second stage. The second stage can be done at any time.

Dr. George W. Crile, Cleveland: I have been an advocate of the two-stage operation, but since Dr. Jones introduced the plan he has described I have had the opportunity of comparing his results with the results secured by the rest of us, as to both the immediate and the late effects. The plan described by Dr. Jones has made the two-stage operation unnecessary. As Dr. Jones has shown, there have been postoperative deaths from shock, but the deaths, when they have occurred, were due to later obstruction. That is a technical matter which can be corrected. I believe that a greater number of permanent cures follow the one-stage operation; that is, it is easier for the patient to have everything done in one stage than to undergo a two-stage operation.

Dr. Fred Rankin, Rochester, Minn.: It should be emphasized, I believe, that any one type of operation for cancer of the rectum must be supplemented by three or four other accessory procedures. I agree with Dr. Jones in his statement that the ideal operation for cancer of the rectum is a combined abdominoperineal resection, whether by one stage or by two. In my experience, however, the applicability of this particular type of operation is not over 25 per cent in the total group of cases as they present themselves. This is a formidable procedure which may not be undertaken without considerable risk in the hands of the most expert and its application necessarily is limited to the best risks, which are in the most cases unobstructed. My second choice is a combined abdominoperineal resection in two stages, a colostomy being done first, with division of the bowel and dropping the distal end back. Secondarily, the resection may be carried out radically and with a satisfactory mortality. Unquestionably, we have all been prone to undertake the second stage too early and I am more and more delaying the resection with the idea that six weeks or possibly more should elapse between the two stages. Thirdly, I think that posterior resection following colostomy will continue to be the operation of choice in the majority of cases, not because one desires particularly to do this type of operation but because it is a procedure which may be carried out in the hands of most men with a low mortality and which will give fairly satisfactory results, even if applied to the whole group of cases. In addition to this, one must occasionally do a local excision, leaving a sacral anus, a procedure to be deprecated except at the patient's insistence. Lastly, a palliative operation with cauterization completes the surgeon's armamentarium. Let me emphasize that the type of operation applicable in rectal cancer is in no sense the type of procedure applicable to cancer of the rectosigmoid. A pointed distinction should be made between these two parts of the bowel because of difference in blood supply and lymphatic drainage. With increasing experience, individualization of cases, and segregation of colon and rectal cases into a single unit, hospital mortality may be reduced to around 10 per cent or even less for all types of operation and increasingly satisfactory end-results expected.

VENOCLYSIS [*]

GEORGE A. HENDON, M.D.
LOUISVILLE, KY.

Venoclysis is a term which I[1] have employed to designate a method for the biologic and continuous administration of physiologic and therapeutic solutions directly into the blood stream. The rate of the flow is regulated so that it will enter the blood stream in accordance with an estimated rate of delivery and distribution. Clinical experiences seem to indicate that for the adult individual this rate is approximately 200 cc. of fluid an hour, or a range of between 4,000 and 5,000 cc. of fluid in the twenty-four hours. The estimate of physiologic tolerance has been based, first, on the fact that patients receiving this amount of fluid at the rate here indicated are free from chills and sudden elevation of temperature, which regularly occur when solutions are suddenly or rapidly introduced directly into the circulation. Secondly, the rise in blood sugar is never more than 200 and then only during the first half hour after the beginning of the treatment when 10 per cent dextrose solution is used. The blood sugar returns to normal in about three hours.

The rate of administration has as much to do with the subsequent results in intravenous therapy as does the substance that is used. I believe it is illogical and perhaps irrational, although it may be expedient at times, to administer a dose as measured by quantity of anything under any circumstances directly into the circulation, because thereby is suddenly imposed on the circulation a burden that it may find impossible or difficult to carry. When a measured quantity of any substance is introduced into the alimentary tract or the subcutaneous cellular tissue, the balance between delivery and distribution is preserved by the physiology of digestion and absorption. In intravenous therapy there is no such physiologic barrier to provide the necessary regulation.

I have found it possible to produce chills by a process that is called "milking the tube." By that I mean making pressure on the delivery tube of the apparatus that will cause a sudden, rapid and intermittent delivery of the solution into the circulation. In addition to my other experiences I regard this as conclusive evidence that the cause of the production of alarming vital reactions following the introduction of physiologic fluids is the factor of time in relation to the volume of fluid introduced. Dosage and tolerance are matters of time as much as they are of quantity and character. One exception can be cited in which rapid introduction may be preferable; that is in transfusing to replace the sudden loss of a large quantity of blood.

PERIOD OF ADMINISTRATION

It must be borne in mind that venoclysis is intended to mean the continuous, uninterrupted, constant, direct administration of fluid into the blood stream. This fluid is presumed to contain sufficient nutritious principles in solution to support the phenomena of life.

The longest period of continuous administration thus far was accomplished by Dr. Frank P. Strickler in a case of purulent meningitis following a mastoid abscess in which he kept the venoclysis going without interruption for twenty-one days. During that time, however, the patient was taking some food and liquids by mouth. In my own experience I was able to maintain the continuous administration in a case of recurrent gastric ulcer for sixteen days during which time the patient received no food by mouth except for one day in the middle of the period, when I transferred the feed from the left basilic to the right basilic vein.

Five days is about the average time that one vessel will remain sufficiently patent to convey the fluid. In exceptional cases I have been able to carry it as long as eight days without changing the vein. Apparently the endothelial surface of the vessel becomes agglutinated after five days and the result is obstruction of the flow and change of veins is thereby made necessary. I find most convenient the basilic and cephalic veins but also use the venae comites and saphenous and superficial veins of the leg below the knee. They all seem to serve with equal facility, and so far there have been no circulatory complications of any importance either local or systemic occurring during or subsequent to the treatment. The period of administration is dependent on the object that I expect to accomplish. For example, experience seems to indicate that from three to five days is necessary to cure a case of emesis gravidarum, while twenty-one days was required in Dr. Strickler's case of meningitis with blood stream infection. From five to sixteen days proved sufficient to control the acute symptoms of peptic ulcer in six cases.

SUBSTANCES EMPLOYED

The substances employed must be in perfect solution and sterile. They must be compatible with the blood. The ingredients of the solution will depend on the indication one is seeking to fulfil. I have used various physiologic solutions but most frequently 10 per cent dextrose in physiologic solution of sodium chloride. Any medication desired can be added to the dextrose or saline solution according to demands. For example, intravenous iron preparations, digifoline, morphine, a soluble barbital compound, calcium and magnesium salts or citrated blood. The latter can be mixed in equal quantities with the dextrose or saline solution. The drugs are administered in solution by injecting them through a hypodermic needle into the delivery tube of the apparatus. I have also added such germicides as metaphen and mercurochrome-220 soluble when indicated. Dextrose is more often indicated than any other one ingredient of the solution. My experience is most abundant in that particular relationship. I generally use a 10 per cent solution because a lower concentration would require an unwieldy volume of fluid to deliver an adequate supply of dextrose, and a higher concentration would increase the viscosity of the fluid and thereby create obstructive difficulties in the process of administration. I am governed in the daily aggregate amount by the appearance of sugar in the urine. This I do not interpret as a signal of alarm but as an evidence that the physiologic demands of the individual have been fulfilled and that to proceed beyond that point would be useless effort and economic waste. I find that patients suffering with severe toxemia and high temperature will consume at least twice as much dextrose in twenty-four hours as those with low temperature and not affected with toxemia. For example, in peptic ulcer cases I found that an average of one-half pound (0.2 Kg.) of dextrose a day seemed to meet their physiologic needs, while in emesis gravidarum and septic infections, 1 pound (0.5 Kg.) a day was the average requirement. Patients with cancer of the colon could consume as much as 11 pounds (5 Kg.) in six days without showing sugar in the urine.[2]

---

[*] Read before the Section on Surgery, General and Abdominal, at the Eighty-First Annual Session of the American Medical Association, Detroit, June 25, 1930.

[1] Hendon, G. A.: Tr. South. S. Soc., 1924; Texas State J. Med. **21**: 662 (March) 1926; Kentucky M. J. **27**: 202 (May) 1929; Tr. South. S. Soc., December, 1929; Ann. Surg. **91**: 753 (May) 1930.

The list of substances that can be used as ingredients of venoclysis solutions is destined to prove an extended one. The work so far has only served to demonstrate the safety and utility of the method and emphasize the value of dextrose when given in quantities sufficient to meet the demands of the system. A patient weighing 150 pounds (68 Kg.) can easily assimilate 2 pounds 0.9 Kg.) of dextrose a day. My experience demonstrates that no patient need ever die of dehydration or starvation alone and that not only life but a fair degree of physical prosperity can be sustained over a period of at least sixteen days without alimentary feeding; that venoclysis renders the physician and patient absolutely independent of the gastro-intestinal canal during a given period. I have every confidence that the time limit of vital sustenance by venoclysis will be substantially increased by greater experience. As demonstrated by Boothby, one can fare very well and perform light work on an exclusive carbohydrate diet for sixty days at least.[3]

Certain phenomena have been observed in the course of my work that are both surprising and unaccountable. In 95 per cent of my cases the red cell count was increased, sometimes very rapidly; in one case, one million the first twenty-four hours and one million and a quarter in the second day, and these increases were maintained in the cases that were followed. One of these was a so-called pernicious anemia in which the patient could not retain food or drugs by the stomach. The other was a simple secondary anemia in which the red blood cell count had dropped down to two and one-half million. The urinary output is nearly always one-half the amount of solution administered. Venoclysis obtunds the sense of hunger. Patients seem to lose all personal interest in food. I have two patients that were confirmed inebriates who completely lost their craving for alcohol after a venoclysis treatment. Bile coloring can be washed out of the tissues in three days. Venoclysis dehydrates the brain and spinal canal in inflammatory and traumatic conditions.[4]

I have used venoclysis with complete success in fourteen cases of emesis gravidarum that were referred to me by my obstetric friends after every other means had been exhausted except the induction of abortion.

Two cases of multiple abscess of the liver were cured, one of which was verified by laparotomy both before and after the treatment and the other was observed and diagnosed by five of the best clinicians.

In two cases of pyogenic blood stream infection the patients were promptly restored to health.

One case of tularemia with extensive axillary adenitis was cured after dissection of the infected glands.

In two cases of meningitis following operation for suppurating mastoid, the pyogenic organisms were found both in the blood stream and in the spinal fluid.

In the past five years I have used venoclysis as a routine for shock, sudden loss of blood, septicemia and all forms of serious surgical toxemias, with the most gratifying results. Its most brilliant achievements have been realized in abdominal surgical conditions in which I also use it constantly, particularly in intestinal obstruction after late operation and for the relief of serious postoperative sequelae and peritonitis from any source, or for deficiency of nutrition or mineral salts, whatever may be its cause. Venoclysis is my method of choice for making blood transfusions because it eliminates the alarming reactions that so regularly occur under other circumstances.

It is ideal as a postoperative treatment following visceral anastomoses. The alimentary canal is placed at rest, peristalsis is inhibited, and opportunity is thereby allowed for union to become established. In six cases of peptic ulcer I have succeeded in controlling dangerous hemorrhage and allaying symptoms as long as a year and a half by a period of five to sixteen day treatment in each case. As a prophylactic against hemorrhage, shock or sepsis, I always employ this measure during as well as after critical operations. In weak and debilitated patients I find that one-half pound (0.2 Kg.) of dextrose a day given by venoclysis three or four days in advance of the operation increases resistance and broadens the margin of safety to a remarkable degree. Its range of usefulness is too wide and varied to be presented here in detail but can be briefly summed up: Venoclysis furnishes a method by which nutrition can be supported independent of the alimentary canal, dehydration prevented, acidosis overcome, infection combated and toxins diluted to a degree of innocuous attenuation.

The apparatus consists essentially of a silver and gold plated cannula. Any size required may be obtained, but the 12 gage is found most frequently useful. Two vacuum bottles suspended from a stand 6 feet high act as reservoirs to contain the fluid and maintain its temperature. A visible rectal dripper is joined in the delivery tube. The rubber tubing used must be of the thick walled stethoscopic variety except for the piece that fits over the cannula. This should be thinner so as to be easily slipped on and off.

[4] Strickler, F. P.: Report of a case before the Jefferson County Medical Society, April 22, 1930.

In preparing the solutions I use physiologic solution of sodium chloride as a vehicle because of its convenience, though I have employed Ringer's solution, Fischer's solution and plain sterile water. Hospitals usually keep a generous supply of physiologic solution of sodium chloride on hand, already sterilized. To this may be added any proportion of whatever ingredient is desired. I use dextrose, which may be sterilized by subjecting the solution to 15 pounds pressure for ten minutes. A supply sufficient for twenty-four hours' use is made at a time.

I endeavor to deliver the fluid into the vein at 100 F. It is placed in the container at from 120 to 130, thus allowing for a loss of from 20 to 30 degrees in transit. Recent experience seems to indicate that temperature is not of as much importance as I formerly believed it to be.

TECHNIC

Any conveniently situated vein will do, but I prefer the basilic or cephalic because, for one reason, they lack tributaries. The vessel is exposed above the elbow by a horizontal incision after a tourniquet has been applied. With an aneurysm needle a convenient length of umbilical tape is carried beneath it. The vein is then ligated with catgut distal to the tape. It is now picked up with mosquito forceps and the tourniquet removed. The portion in the grasp of the forceps is snipped with a manicurist instrument known as a cuticle nipper. This enables one to lift up a tongue of triangular shaped tissue composed of vessel wall. Through the opening thus made the specially devised cannula is introduced beyond its shoulder and the tapes encircling the vessel are tied, one proximal and the other distal to the shoulder. The cannula thus secured is then connected by a piece of rubber tubing and a glass irrigating nozzle to the delivery tube and the flow is started at a rather rapid dropping rate and immediately throttled down to about forty drops a minute. The rectal dripper serves to permit one to count the drops and register the amount. When I am assured that the connections are patent and the flow established, the tubing is bound to the forearm with encircling strips of adhesive plaster to the wrist. No splints are either desirable or necessary; the patient may assume any position he finds most comfortable. Two vacuum bottles to act as reservoirs are provided so that there need be no interruption in the supply. As soon as one becomes empty the alternate is turned on and the exhausted flask is refilled immediately.

Regarding the blood sugar content during venoclysis, information has been furnished me by Dr. W. T. McConnell[5] from his records taken from fifteen of his own personal cases. He made eight readings from each case at half hour intervals and for venoclysis of 10 per cent dextrose solution the following results were obtained: The first reading one-half hour before beginning the venoclysis averaged 120 mg. The first half-hour after beginning venoclysis showed 200, the second 175, the third 150, the fourth 135, the fifth 130, the sixth 120, the seventh 120, the eighth 120. These figures seem to prove that venoclysis is physiologically and biologically correct and that it possesses a decided and extended clinical value that cannot be obtained in any other way.

SUMMARY

1. Venoclysis furnishes a safe, simple and efficient method of supplying nutritious fluids or medicine directly into the circulation in any quantity that may be desired.
2. Venoclysis enables one to preserve the ratio between delivery and distribution, thereby eliminating the group of shock symptoms called reactions.
3. Venoclysis permits the use of commercial dextrose, which is an important economic consideration.
4. Venoclysis allows the administration of adequate dextrose and sufficient fluid to sustain life without the functions of the alimentary canal being exercised.
5. Venoclysis offers the safest plan for the transfusion of blood.
6. Venoclysis offers the most logical means of combating blood stream infection with germicides and dilution of toxins.
7. Venoclysis is the surest and quickest way known to gain a substantial and permanent increase in red blood cells and to dehydrate the brain and cord in traumatic and inflammatory conditions.

321 West Broadway.

ABSTRACT OF DISCUSSION

Dr. Lucian H. Landry, New Orleans: Some obstetricians have advocated the addition of insulin when giving dextrose intravenously by the drip method in the treatment of hyperemesis gravidarum and the toxemias of pregnancy. I have not found this to be necessary, since the glycosuria and glycemia following the prolonged administration of 5 per cent dextrose by the drip is only slight and transitory. I can also confirm Dr. Henry J. John in his advocacy of the use of dextrose with insulin in the treatment of diabetic patients needing surgery, though we scarcely exceed the usual 5 per cent solution except in cases in which renal insufficiency complicated the diabetes, when dextrose is administered in larger doses (Enriquez solution) as a diuretic. The blood sugar can be easily controlled by the use of insulin, the intravenous dextrose rendering great aid in overcoming the acidosis and increasing the excretion of acetone bodies through the urine. While we depend on dextrose almost exclusively for our routine solution, we recognize that there are special indications for saline or mixed salt and sugar solutions, which are not met by dextrose alone. The salt is especially indicated in acute intestinal obstruction for the relief of the hypochloremia. Hypertonic salt solutions may be used as suggested by Weed (25 per cent) in cases of cranial injury with contusion and compression, but even here I prefer the hypertonic dextrose (25 to 30 per cent) for short infusions not exceeding 500 cc. at a time. This, in combination with magnesium sulphate by mouth, can be depended on as a sufficient cerebral dehydrant. Gally and Harris (*Ann. Surg.* **91**:422 [March] 1930) show a fear of dextrose for intravenous use which is not justified by clinical experience. Of course it goes without saying that hypertonic or supersaturated salt (20 per cent sodium chloride, Linser's solution) or sugar (from 30 to 50 per cent dextrose, Nobl's solution) will cause sclerogenic processes when injected into veins, and for this reason are used advantageously for the treatment of varicose veins; but this does not apply to the isotonic solution, 5 per cent, which I use for the continued drip. Our experience of twelve and more years, with the continued dextrose drip, kept up days and sometimes weeks in hundreds of cases, have never been followed by postoperative pulmonary embolism or thrombosis. My experience is in accord with others that the free use of dextrose in the continuous drip not only is superior to salt in many ways but, from a clinical point of view, may be regarded prophylactically as an antithrombotic agent. While it has been shown experimentally that dextrose solution shortens the coagulation time in cholemic states and obstructive jaundice, it has also been shown that a thrombophilic state of the blood is induced by a protein diet, while the coagulability of the blood is not increased by a hydrocarbon (dextrose) and fat diet.

---

[5] McConnell, W. T.: Personal communication to the author.

Dr. J. C. Ray, Louisville, Ky.: It is needless for me to verify the number of statements just made by Dr. Hendon regarding venoclysis because he has full proof of the procedure and results in most of the cases. Dr. Hendon has used successfully venoclysis in a number of cases that were considered hopeless by many physicians associated with the work. May I mention a few criticisms that have been brought against venoclysis by men who have only a few times observed its reaction? First, that a patient may drown because of the large quantity of fluid that is used. This is known to be untrue, because many of the patients who have had venoclysis are now living. A few postmortems that I made showed that the cavities had no excess of fluid and that the lungs were crepitant throughout; I considered that we had not drowned these patients. Another criticism offered by some physicians is that the patient suffers by the continuous administration necessary. It was my privilege to help Dr. F. P. Strickler with a patient. There were twenty-one days of administration, beginning with an unconscious patient who had meningitis with streptococcus and staphylococcus culture from the spinal fluid and the blood stream. There was an increase of spinal fluid pressure to something like 40 mm. of mercury. Within less than forty-eight hours the patient's temperature had dropped only a small amount, and the patient was able to read a paper with a temperature of from 103 to 104 F. In this particular case, we used the left arm vein once, both veins of the right arm, and one vein in each leg during the twenty-one days of administration. It has also been said that the fluids or feedings should be given at certain intervals. Does the intestinal tract empty everything into the blood stream all at once? The continuous administration of the dextrose into the blood stream is a physiologic fact.

Dr. Paul Titus, Pittsburgh: I have long thought that single injections of strongly hypertonic dextrose solutions are preferable to prolonged injections of weak solutions, termed venoclysis by Dr. Hendon, because the latter will frequently cause certain types of reactions unless given exceedingly slowly. Largely as the result of Dr. Hendon's excellent work on venoclysis, I am now convinced that there is also a distinct place for this type of injection which he has described. Woodyatt, Wilder and Sansum have shown that the body cannot utilize dextrose injected faster than 0.8 Gm. per kilogram of body weight an hour. Other work has demonstrated that from 75 to 100 Gm. of dextrose should be about the maximum dose at this rate. If given faster or in larger amounts, loss by kidney occurs as well as an undue stimulation of the pancreatic function, with an outpouring of endogenous insulin in excessive amounts which may frequently produce the result of a sharp hypoglycemic reaction. Such a reaction is similar to those seen fairly frequently following dextrose test meals. Dr. Hendon did not have sufficient opportunity to emphasize that in prolonged venoclysis the injection rate must be several times slower even than that for the single injections in order to avoid these reactions as he has been able to do. The common fault in the average intravenous injection of dextrose is that it is almost invariably given dangerously fast. The single injections of maximum amounts of dextrose solutions at maximum rates are by no means to be discarded in favor of this method just described, but venoclysis offers an additional choice of methods of intravenous administration of dextrose especially adapted to cases in which marked dehydration is a factor. The older method will probably continue to be the method of choice in the majority of instances, although there are certain types of cases in which venoclysis is to be preferred.

Dr. G. A. Hendon, Louisville, Ky.: I did not have time to refer to the sources of my information, but they will appear in the bibliography. I sought to give credit to everybody who has contributed to this important subject. Dr. Landry particularly brought out Dr. Matas's work, which I have acknowledged in my references as the foundation of my information. Dr. Landry made the observation that the sugar would not support life indefinitely. We do not live that long under any circumstances.

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

The following additional articles have been accepted as conforming to the rules of the Council on Pharmacy and Chemistry of the American Medical Association for admission to New and Nonofficial Remedies. A copy of the rules on which the Council bases its action will be sent on application.

W. A. Puckner, Secretary.

AMYTAL. — Isoamylethylbarbituric acid. — Isoamylethylmalonylurea. — 2,4,6-trioxy-5-isoamylethylpyrimidin. — $C_5H_{11}(C_2H_5)\underline{C\ CONH\ CONH\ CO}$. Amytal differs from barbital (diethylbarbituric acid) in that one of the ethyl groups of the latter is replaced by an iso-amyl group in the former.

Actions and Uses.—The actions and uses of amytal resemble those of barbital. It is proposed as a sedative and hypnotic in the control of insomnia and as a preliminary to surgical anesthesia.

Dosage.—It is given orally in tablet form with water or hot milk. As a sedative: 0.02 to 0.04 Gm. (⅓ to ¾ grain) two or three times daily. As a hypnotic: 0.1 to 0.3 Gm. (1½ to 5 grains) one-half to one hour before sleep is desired. For use before local or general anesthesia the dosage ranges between 0.2 and 0.6 Gm. (3 to 10 grains), being determined by a large number of factors (age, etc.). It can be used safely for such purposes only by those who have had much experience and are familiar with the literature concerning such use. As an antispasmodic in tetanus, 0.4 to 0.8 Gm. (6 to 12 grains) may be required to control convulsions. In some patients barbital derivatives produce restlessness and excitement, and to these patients amytal should not be administered.

Manufactured by Eli Lilly & Co., Indianapolis, Ind. U. S. patent 1,514,573 (Nov. 4, 1924; expires 1941). U. S. trademark 161,125.

Tablets Amytal, 1½ grains.

Amytal occurs as a white crystalline, odorless powder, with a slightly bitter taste; completely soluble in alcohol and ether; very slightly soluble in cold water; insoluble in the paraffin hydrocarbons. A saturated aqueous solution is acid to litmus paper. It melts at 153-155 C.

Place 0.3 Gm. of amytal in a 25 cc. glass stoppered cylinder, add a mixture of 1 cc. normal sodium hydroxide solution and 5 cc. of water, shake the contents for one minute, filter through paper and divide into two portions; to one portion add 1 cc. of mercuric chloride solution: a white precipitate results, soluble in 10 cc. of ammonia water; to the other portion add 5 cc. of silver nitrate solution: a white precipitate results, soluble in 5 cc. of ammonia water. Boil 0.5 Gm. of amytal with 5 cc. of a 25 per cent sodium hydroxide solution: it is decomposed with the evolution of ammonia.

Dissolve 0.1 Gm. of amytal in 1 cc. of sulphuric acid: the solution is colorless (*readily carbonizable substances*). Boil 0.5 Gm. of amytal with 50 cc. of water for two minutes: no odor develops; cool and filter: separate portions of 10 cc. each of the filtrate yield no opalescence with 1 cc. of diluted nitric acid and 1 cc. of silver nitrate solution (*chloride*); no turbidity with 1 cc. of diluted nitric acid and 1 cc. of barium nitrate solution (*sulphate*); no coloration or precipitation on saturation with hydrogen sulphide (*salts of heavy metals*).

Incinerate about 1 Gm. of amytal, accurately weighed: the residue does not exceed 0.1 per cent. Dissolve about 0.5 Gm. of amytal accurately weighed, in 25 cc. of previously neutralized alcohol; dilute with an equal volume of water and titrate with tenth-normal sodium hydroxide solution, using thymolphthalein as an indicator: the amount of tenth-normal sodium hydroxide solution consumed corresponds to not less than 98.5 per cent nor more than 101.5 per cent of isoamylethylbarbituric acid.

PULVULES SODIUM AMYTAL, 3 GRAINS.—Gelatin capsules ("pulvules") each containing 0.2 Gm. (3 grains) of sodium amytal, the monosodium salt of isoamylethylbarbituric acid.

Actions and Uses.—The actions and uses of pulvules sodium amytal, 3 grains, resemble those of barbital. The product is proposed as a sedative and hypnotic in the control of insomnia and as a preliminary to surgical anesthesia.

Dosage.—As a potent sedative or hypnotic, 1 "pulvule" (capsule), equivalent to 0.2 Gm. (3 grains), repeated if necessary at intervals of six hours. For use before local or general anesthesia the dosage ranges between 1 and 3 pulvules, 0.2 to 0.6 Gm. (3 to 9 grains), being determined by a large number of factors (age, etc.). It can be used safely for such purposes only by those who have had much experience and are familiar with the literature concerning such use. As an antispasmodic in tetanus, from two to four pulvules, 0.4 to 0.8 Gm. (6 to 12 grains), may be required to control convulsions. In some patients barbital derivatives produce restlessness and excitement, and to these patients pulvules sodium amytal, 3 grains, should not be administered. The pulvules may be administered by mouth, or, if necessary, the same dose given rectally, the pulvules being inserted as suppositories or the contained powder dissolved in a little water and administered.

Manufactured by Eli Lilly & Co., Indianapolis, Ind. U. S. patent 1,514,573 (Nov. 4, 1924; expires 1941). U. S. trademark 161,125.

Sodium amytal occurs as a white, friable, hygroscopic odorless granular powder with a slightly bitter taste; very soluble in water; freely soluble in alcohol about 1 part in 1 part; practically insoluble in ether.

Dissolve about 0.5 Gm. of sodium amytal in 100 cc. of water, add an excess of diluted hydrochloric acid; collect the resultant isoamylethylbarbituric acid on a filter, wash and dry: it melts at 152-155 C. Incinerate about 1 Gm. of sodium amytal: the residue responds to tests for sodium carbonate. Boil about 0.5 Gm. of sodium amytal with 5 cc. of a 25 per cent sodium hydroxide solution: it is decomposed with the evolution of ammonia. Dissolve about 0.3 Gm. of sodium amytal in 10 cc. of water and divide into two portions; to one portion add 1 cc. of mercuric chloride solution: a white precipitate results, soluble in an excess of ammonia; to the other portion add 5 cc. of silver nitrate solution: a white precipitate results, soluble in 5 cc. of ammonia water.

Dissolve about 0.5 Gm. of sodium amytal in 50 cc. of water, add 5 cc. of diluted nitric acid and filter through paper: separate portions of 10 cc. each of the filtrate yield no opalescence on the addition of 1 cc. of silver nitrate solution (*chloride*); no turbidity on the addition of 1 cc. of barium nitrate solution (*sulphate*). To about 0.2 Gm. of sodium amytal in 25 cc. of water, add 1 cc. of diluted hydrochloric acid, filter through paper: the filtrate yields no coloration or precipitation on saturation with hydrogen sulphide (*salts of heavy metals*). Add about 0.2 Gm. of sodium amytal to 1 cc. of sulphuric acid: the solution is colorless (*readily carbonizable substances*). Transfer about 1 Gm. of sodium amytal, accurately weighed, to a glass stoppered cylinder, add 50 cc. of anhydrous ether, stopper, shake the contents for ten minutes; decant the supernatant liquid through filter paper, and repeat twice, using first 25 cc. and second 15 cc. of ether and utilizing the same filter; evaporate the combined filtrate to dryness in a tared beaker and dry to constant weight at 100 C.: the residue does not exceed 0.2 per cent (*uncombined isoamylethylbarbituric acid*).

Dry about 1 Gm. of sodium amytal, accurately weighed, to constant weight at 100 C.: the loss does not exceed 1 per cent. Transfer about 0.5 Gm. of sodium amytal, accurately weighed, to a suitable Squibb separatory funnel, add 50 cc. of water, followed by the addition of 10 cc. of diluted hydrochloric acid, extract with eight successive portions of ether, using 25 cc. each, evaporate the combined ethereal extractions to dryness in a stream of warm air and dry to constant weight at 100 C.: the amount of isoamylethylbarbituric acid corresponds to not less than 90 per cent nor more than 91 per cent, calculated to the dried substance. Weigh accurately about 1 Gm. of sodium amytal in a tared platinum dish, add 5 cc. of sulphuric acid, heat cautiously until the excess of sulphuric acid has been volatilized; repeat twice, using 1 cc. of sulphuric acid each time, add about 0.5 Gm. of ammonium carbonate, ignite to a constant weight and weigh as sodium sulphate: the percentage of sodium corresponds to not less than 8.9 per cent nor more than 9.5 per cent when calculated to the dried substance.

COMMITTEE ON FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COMMITTEE ON FOODS OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION, AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

RAYMOND HERTWIG, Secretary.

ARGO CORN STARCH

Manufacturer.—Corn Products Refining Company, New York.

Description.—A refined corn starch of high purity.

Manufacture.—Shelled corn, cleaned free of foreign material, is covered over with water and allowed to stand in tanks to soften for thirty to forty hours. The water with dissolved proteins, sugars and other soluble matter is drawn off.

The softened corn is washed and cracked or broken in attrition mills. The germ and coarser hull are separated out by means of germ separators and bolting reels. The remaining material is ground in burrstone mills to loosen completely the adhering hull. The fine ground mixture is passed over shakers clothed with fine mesh silk to separate out the fine hull particles. The hull free starch and gluten material passes through, is mixed with water and flowed over slightly inclined wooden tables. The starch settles out by gravity and deposits on the tables, whereas the gluten and water flow off.

The starch on the tables is flushed with process water which brings it into suspension. It is again deposited on the tables or washed in continuous filters with fresh water, which removes considerable admixed soluble material. The starch is removed from the filters or tables, dried in kilns (twenty-four hours), milled to a powder, bolted to remove coarse particles and finally packed by automatic machines.

Composition.—

	Per Cent
Moisture	12.5
Ash	0.15
Protein (N × 6.39)	0.3
Fat (ether extract)	0.1
Starch (by difference)	86.95

Calories.—

3.50 per gram.
99.4 per ounce.
1,590. per pound.

Claims of Manufacturer.—Argo corn starch is recommended for use in puddings, custards, ice cream, a wide variety of desserts, in bakery products, and for thickening gravies, sauces, pie filling, stewed fruits, etc.

DROMEDARY GOLDEN DATES (PITTED AND PLAIN)

Manufacturer.—The Hills Brothers Company, New York.

Description.—Pasteurized pitted or plain Mesopotamian dates in cartons.

Preparation.—The dates are mechanically graded at Basrah, Mesopotamia, packed in boxes and shipped to Brooklyn. The largest and most perfect dates are selected for the Dromedary Brand.

The selected dates, pitted or plain, are washed, and pasteurized in ovens under definite temperature and humidity conditions for a fixed period of time. Nonsporulating bacteria do not survive the treatment. (Numerous laboratory experiments show that temperatures of 160-185 F. at humidities of 70-100 per cent for from thirty to ninety minutes are effective for reducing the molds and bacteria 93 to 99 per cent.) The pasteurized dates are sealed in wax-paper in cartons and again pasteurized.

Composition.—Pits constitute 12.8 per cent of plain dates. Pitted dates:

	Per Cent
Moisture	19.0
Ash	2.2
Protein (N × 6.25)	1.7
Fat (ether extract)	1.9
Sucrose	0.0
Reducing sugars as invert	73.5
Crude fiber	2.2
Total carbohydrates (by difference) other than crude fiber	73.0
Sulphur dioxide	0.0

Calories (pitted dates).—

3.16 per gram.
89.7 per ounce.
1,435. per pound.

Claims of Manufacturer.—The pasteurization, without injury to flavor or texture, destroys nonsporulating bacteria which may accompany dates and therefore makes them a safe food. They may be eaten direct from the package, used in baked goods, cooked with cereals, or served in a wide variety of food preparations. Dromedary Dates are an easily digested energy food for children and adults.

The Diagnostic Clinic at Its Best.—The latest substitute for the breadth of vision of the general practitioner is that offspring of the American god of efficiency, the Diagnostic Clinic. What a strong appeal it makes, this apparently ideal combination of a group of specialists so closely affiliated as to afford all the advantages of expert knowledge and at the same time maintain the desirable general supervision! Practically the method seems to work out about like most substitutes—sometimes well and sometimes badly. It all depends upon the men who constitute the group. At its best the patient finds himself in the hands of a wise, broadly trained physician who handles his case personally and refers as occasion demands to intimate and trusted associates who are skilled in special fields. One man has personal supervision over the case and devotes enough time to it to grasp all of its ramifications, so that he can estimate the relative importance of the findings of the specialists on the production of the symptoms in the individual. —Peabody, F. W.: Doctor and Patient, New York, Macmillan Company, 1930.

SATURDAY, OCTOBER 18, 1930

NATIONAL INSTITUTE OF HEALTH

On May 26 the President attached his signature to the act establishing the National Institute of Health. This bill, sponsored by Senator Joseph E. Ransdell, was approved by the American Medical Association and actively supported by practically every organization devoted to the advancement of human welfare. In accordance with the act, the Hygienic Laboratory of the Public Health Service, with its long record of accomplishments, is merged into a new institution with well nigh unlimited opportunities for scientific research.

Originally attached to the marine hospital in New York as a small clinical office, the Hygienic Laboratory was founded in 1887, when the world heard with astonishment of the menace of germs as agents of disease. The laboratory passed under a variety of names until 1901, when Congress gave it a place in governmental nomenclature by appropriating a small sum for an experimental building and directing that the institution should "investigate matters pertaining to the public health." This broad authorization has produced singularly happy results. The first large undertaking was to put the commercial production of vaccines, serums and analogous products on a safe and scientific basis; in cooperation with responsible business concerns, a system of inspections and licensing was established. So thoroughly has this plan been developed that today the practicing physician in the most remote section of the country has ready access to dependable biologic products for administration to his patients.

The Hygienic Laboratory's contributions to the betterment of human health speak for themselves. The essential cause of pellagra was worked out at the laboratory and its field stations. This clearly pointed the way to both prevention and cure, so that at present this disease may be said to be no longer a medical problem but an economic one. Early studies of anaphylaxis, a word which, by the way, was coined at the Hygienic Laboratory, brought the phenomenon of hypersusceptibility to the attention of research workers throughout the world. The investigations into the nature of measles, conducted some years ago, resulted in cutting the period of quarantine from twenty-one to ten days, with a consequent gain in school and earning capacity. The recent discovery of a vaccine against Rocky Mountain spotted fever has proved of great financial value to the infected areas of the Northwest. The recognition, etiology and prophylaxis of tularemia represent the only instance in which American physicians alone have solved the complete entity of a disease. A review of the activities of the Hygienic Laboratory in medical research would comprise many columns of print and would reach into the fields of chemistry, pharmacology, zoology, the biologic sciences and a wide range of subjects intimately concerned with the mysteries of health and disease.

The National Institute of Health, therefore, comes into a rich inheritance. It assumes at once the potentialities of a well organized institution with a number of problems under investigation and many others awaiting attack. Functioning under the Treasury Department through the Public Health Service, the institute is placed in a position both conservative and authoritative. The Secretary of the Treasury is authorized to accept, either by will or otherwise, donations from philanthropic sources for the purpose of carrying forward studies, investigations and research in the fundamental problems of diseases of man and matters pertaining thereto. Funds so contributed are in the close control of the government and should be wisely administered for the public good. Donations of $500,000 or over in aid of research will be acknowledged permanently by the founding of suitable memorials to the donors. A system of fellowships is provided for the utilization of such funds. Already the Chemical Foundation has contributed $100,000 to provide for one or more fellowships in chemistry.

Many critics have expressed doubt as to whether or not the government should undertake research supported by private contributions from commercial agencies. It will require the most stringent safeguards to insure absolutely scientific study, honest, unrestricted reporting of results and proper distribution of the fruits of discovery. The development of such procedure should be among the first steps taken in furthering the work of the institute.

Provision is made for expansion in the way of buildings and for the appointment of scientists, who may be chosen for the prosecution of investigations anywhere in the world. Of great importance is a provision that the facilities of the institute shall be available to health authorities of states, counties or municipalities for purposes of instruction and investigation.

The array of problems awaiting solution is imposing. The so-called constitutional diseases, infections of remote or unknown etiology, cellular proliferation and inhibition, and nutritional studies will be taken up at once. The aspects of chemistry in relation to health and disease comprise a field for fundamental research to which the institute has already turned its attention. Biologic processes applied to insect vectors of disease and to principles of immunity and susceptibility are inviting lines of research. Scores of specific problems might be mentioned. The National Institute of Health may well become a responsible organization in the field of medical research, contributing discoveries of untold benefit to man.

MENTAL HYGIENE

The functions of the nervous system involve an intricate maze of activities: the physiologic adjustment of our body to its environment, with association, correlation and synchronization of the various activities of our several organs and our conscious or mental life. A complete understanding of these mechanisms remains one of the most perplexing of scientific problems. Nevertheless, guides are available including certain precautions necessary for maintaining the nervous system in a healthful state. For this hygiene of the nervous system the mastering of a large amount of intricate details of anatomic structure and physiologic function is not necessary.

The adaptability of the mind has intrigued the interest of mankind for many centuries. Environmental observations, experiences and sensations have always been rationalized. Explanations have been sought and interpretations adopted that gave the greatest degree of satisfaction in keeping with the traditions, customs and spirit of the times. During the so-called early prehistoric period, man probably did not speculate much about his origin or why he lived. His works of art during that period do not indicate a familiarity with those speculations and superstitions concerning the metaphysical that so enriched the art of a later period.

Disorders and deviations in the functioning of man's brain were long interpreted, with a coloring of awe and fear, as the result of magic spells or malign influences. Mental alienation was explained as supernatural, preternatural or "touched by God." Thus, these more "fortunate" persons were permitted to wander in freedom or were endowed with immunity and special privileges in the matter of conduct or behavior. Those who threatened the social order were, however, condemned to death, to isolation or to restraint. Seldom does one find an educated person today who believes that mental alienation is the result of the malign influences of evil spirits, witchcraft, the moon or other mysterious agencies; nevertheless there still prevails a general impression of mystery about a mentally disordered person, which produces in others a feeling of awe and fear.

As early as 460 B. C., Hippocrates recognized the alcoholic insanities, described epilepsy and delirium, and instituted certain forms of treatment for those with mental disease. To Pinel, however, is given the credit for the more humane method of treatment for the insane, although hospitals for the care of mentally disordered persons had been erected in Spain some two centuries earlier. The humane methods adopted by Pinel in the treatment of the insane at Salpêtrière were simultaneously adopted by De Quin at Savoy. Similar reforms were instituted at San Bonifaccio in Florence and by Tuke in York, England. These reforms were the torchlights for analytic studies of the symptoms of mental diseases. Thus the nosologists, following the true traditions of medical progress established by Galen, Zacchias and Willis, observed, recorded and classified their observations and gave to medicine the framework of clinical psychiatry. With studies of the gross and microscopic anatomy of somatic diseases, the principles of bacteriology and pathology were applied in an effort to understand disorders of the mind.

Such an approach led to a better understanding of structural alterations of the brain associated with encephalitis, dementia paralytica, senility, arteriosclerosis, Huntington's chorea, toxic delirious states and other organic brain diseases. In this direction, however, the harvest of knowledge has been less spectacular and less prolific than that yielded by a similar approach to the understanding of other somatic diseases. These differences in yield have been due to the great difficulty and complexity of evaluating these so-called materialistic observations as they relate to the function and structure of the nervous system. Perhaps the lack of precise means and methods, or the inability to interpret the results, constituted factors instrumental in swinging medical interests away from a structural and materialistic approach to the problems of mental disease. Thus, more attention was directed to the study of the social and environmental influences and the effects of past experiences that influence an individual's later mental reaction. As the result of such an approach there has developed a series of interpretations which, for convenience, has been designated "psychogenetic philosophies." Such an approach has been the means of explaining the mechanism of mental alienation or mental illness, but much of this explanation savors of being nonmedical, if not unmedical, in its approach. Much chaff has accompanied this harvest, resembling in many respects the "magic art" of another day.

The necessity for keeping the banners of medicine over the mentally ill is best illustrated by the resolutions passed by the Section on Nervous and Mental Diseases of the American Medical Association during its recent meeting in Detroit. These resolutions point out that the problems of mental disorders and mental defectiveness and the subject of mental hygiene constitute one of the most serious situations with which scientific medicine is at this time concerned. The Section on Nervous and Mental Diseases recommended to the House of Delegates that the Board of Trustees of the

American Medical Association be authorized to appoint a special committee of five Fellows of the Association interested in these problems with a view to an investigation of the situation and to the making of a report to the Board of Trustees on the manner in which the American Medical Association can be of service in the solution of these problems.

On June 14 the President signed a bill which establishes a Division of Mental Hygiene in the Office of the Surgeon General of the Bureau of the Public Health Service in the Treasury Department, and authorized the Surgeon General to make such studies and investigations as may be necessary of the abusive use of narcotic drugs; of the quantities of crude opium, coca leaves and their salts, derivatives and preparations necessary to supply the normal and emergency medicinal and scientific requirements of the United States; and of the causes, prevalence and means for the prevention and treatment of nervous and mental diseases. The fact that the Congress of the United States has recognized that mental disorders constitute a problem of national health again indicates the necessity for awakening the medical profession to a sober and scientific approach to the problems of the causes, prevalence and means for the prevention and treatment of nervous and mental diseases.

EAT AND STAY THIN

Many features about the body weight are far from being adequately understood. One frequently hears it stated that the body weight is primarily the result of a sort of physiologic bookkeeping, representing the balance between the intake and the outgo of matter. This is determined in turn by the body's need and use of energy-yielding material. Certain functions by which we live and work call for food fuel; others require suitable substances for the replacement of effete matter—the wear-and-tear quota of the body; and when growth also is involved, nutrients must be retained to meet its demands. Intake of food fuel beyond these requirements almost always results, so we have been told, in deposition of the excess. There are exceptions attributable to the effect of the "whipping up" of metabolism by the foodstuffs, notably the proteins. This is currently spoken of as the "specific dynamic action" of foods. It represents a minor factor under the usual conditions of living. Accordingly, as Wilder[1] has recently remarked in an examination of the conventional point of view, if one's energy exchange each day was 2,000 calories and if one should eat in excess of this amount as little as 90 calories of fat or carbohydrate, this would "stick to the ribs," so to speak, and this amount (10 Gm. of fat) accumulating day after day would mean in the course of ten years not less than 36,500 Gm., or 80 pounds, of extra weight. The 90 calories of excess food, causing this monstrous result, would be contained in a small pat of butter or a single chocolate cream of one of the more luxurious varieties.

Many persons do grow fat. The struggle against obesity is brought vividly to the attention of almost every physician by the complaints of patients who demand to be relieved of the consequences of excessive eating. Investigators have searched for evidence of some abnormality in the metabolism of the obese, but without success. The metabolism of rest, or the basal metabolism, when measured as calories for each square meter of body surface, has been found to be no different in fat and in thin subjects. In simple obesity there is no abnormality of the basal metabolic rate.

Perhaps even more surprising than the widespread occurrence of obesity is the failure of many persons to grow fat under conditions of eating and activity that would lead one to expect the nutritional balance to be favorable to gains in weight. Eating has become, to quote Mrs. Rose, the favorite indoor sport of Americans. Overeating has become a habit with thousands, yet they escape adiposity. Wilder has presented this situation by the remark that there must be some device other than appetite to regulate body weight, because we continue to be protected against obesity, most of us, even though we hoodwink our appetite by various tricks, such as cocktails and wines with our meals. The whole artistry of cookery, in fact, is developed with the prime object, he adds, of inducing us to eat more than we ought. Why, then, do we not all grow fat?

The answer is not easily formulated. In accord with several other modern investigators, Wilder believes that the older physiologists overlooked something important, and that food in excess of what may be called the actual requirements is not deposited by people who stay thin. This brings a return of the old theory of luxus consumption, the burning up of food to rid the body of an undesired excess. It is well known that hyperthyroidism leads to increased metabolism and in many instances to loss of weight. Also epinephrine, secreted by the suprarenals, has a calorigenic action. Its effect is more rapid and sooner over than that of the secretion of the thyroid, but, like thyroxine, it accelerates metabolism. Thin persons are likely to be "nervous" and temperamental, in contrast with the phlegmatic disposition that so often goes with obesity. Emotional stress may lead to liberation of epinephrine; hence the heat production and food fuel waste may be accelerated. According to Wilder there is considerable evidence that this is true and that the individual who gains weight readily reacts to stimuli less intensively, that is, with the liberation of less epinephrine, than one who has no such tendencies. Obesity, he remarks, may not be just a matter of excessive eating. Some abnormality, possibly an inadequacy of the mechanism of luxus consumption, must be present to account for the inability to rid the body effectively of excesses of food.

These facts do not alter the fundamental features of the treatment of obesity. These consist, as has been stressed before in THE JOURNAL,[2] in restricting the intake to below the calorific requirement of the individual. A good working rule is to regard the values of the actuarial tables as minimal optimal values for persons under 30 and maximal optimal values for persons over this age. The guiding principle is to reduce the total calories of the intake and at the same time provide adequately of vitamins and proteins. It is wise, perhaps, to overdo, or at least supply the vitamins abundantly and, except in cases complicated with nephritis and hypertension, to supply protein liberally; that is, in amounts approximating 100 Gm. a day. This is important in order to provide against loss of body protoplasm, also because of the satiety value of meat, and because of the desired high specific dynamic action of meats which are rich in protein. The dicta of Wilder deserve repetition:

---

[1] Wilder, R. M.: The Management of Obesity, J. Am. Dietet. A. 6: 91 (Sept.) 1930.

> The intake must be curtailed and the chief problem, then, is how to accomplish this with a minimum of discomfort and without injury. The technic of the procedure is exactly like that which is followed in the management of diabetes. The patient must be trained. Without his intelligent cooperation, nothing happens. He also must want to reduce, and he must understand how to do it. It is usually wiser, the ultimate results being better, if weight is lost very gradually. A too rapid reduction may impair strength of heart or nervous system—the patient feels uncomfortable, loses confidence, and stops the treatment. A reduction which requires more time results in establishing new food habits, so that afterward the patient finds himself able to hold his new weight without conscious effort. In some cases, it seems as though prolonged dieting restores to normal the ability to metabolize food in excess of requirements, that is, the luxus consumption referred to above, so that previously forbidden sweets and fats can be indulged in again without gaining. A weight loss of two pounds a week is as much as should be sought, and one pound is quite enough after the first ten or twenty pounds have vanished.

Current Comment

EFFECT OF DIET ON GROWTH OF FIBROBLASTS

To what extent is it possible to influence the growth of tissues or the development of organs by alterations in the composition of adequate diets? A possible answer to this question has provided the stimulus for many investigations. In view of the various mechanisms in the body whose activity tends to maintain a uniform composition of the nutrient body fluids, it would appear at the outset that little promise of positive results might be expected. Certainly, the alluring hope of controlling the growth of malignant neoplasms through dietary adjustments has received little encouragement from the results of investigation. On the other hand, there is evidence that in the healing of superficial wounds and in the repair of damaged tissues of certain organs there is an accelerating effect of diets rich in protein and a retarding influence of rations containing large amounts of fat. The most recent contribution to this field is that of Harvey and Howes,[1] who report that a complete ration unusually rich in protein favors a more rapid rate of growth of fibroblasts in a healing wound than does a diet with the usual concentration of protein. White rats were used as experimental animals and the wound, a simple incision in the stomach wall, was tested for strength at various intervals after the operation by an ingenious method of inflation of the excised organ. The pressure at which the wound broke served as the index of rate of healing; hence of growth of fibroblasts. During the first four days after the operation—the latent period—no influence of the high protein diet was manifest, but from the fifth to the tenth days there was a decided increase in rate of healing in the group given the protein-rich food. Since it was shown that a difference in energy consumption was not correlated with the changes in velocity of growth of fibroblasts, one is led to believe that here again is evidence of an influence of diet on tissue growth.

THE MEASUREMENT OF VENOUS PRESSURE

Although clinicians are continually concerned with the measurement of arterial blood pressure and are frequently interested in the capillary pressures, one rarely hears of any quantitative consideration of the venous pressures in man. This negligence of the subject cannot be due to any lack of significance of the dynamics of venous blood flow. The venous pressure, which is much influenced by the efficiency of the heart as a pump, has been regarded as one of the most delicate tests of cardiac competence. A rise in venous pressure is common in cardiac diseases, and the venous congestion so produced may have serious consequences. Other interferences with the venous return of blood to the heart are familiar. The failure to measure the pressures existing within the veins more frequently has presumably been due to the inherent difficulties or inconveniences of the available methods. Taylor, Thomas and Schleiter[2] of the Allegheny General Hospital in Pittsburgh have devised a comparatively simple technic involving direct reading of the ascent of the venous blood in a vertical glass tube connected by a hypodermic needle with the lumen of the vessel. Strangely enough, this is a return to the classic method of Stephen Hales, who in 1735 inserted tubes into the jugular vein of a mare and observed the resultant rise of blood. The measurements on healthy persons yielded values between 4 and 10 cm. of blood, with most of the figures ranging between 6 and 8 cm. The average would approximate 5 mm. of mercury, in terms of the customary unit of expression for arterial tension. Perhaps the new methods alleged to possess simplicity, reasonable accuracy and freedom from error of a personal nature will find a useful clinical application in circulatory disorders.

Association News

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Talks

The American Medical Association broadcasts at 10 a. m. on Monday, 10:15 on Tuesday, and 10 on Saturday, over Station WBBM (770 kilocycles or 389.4 meters).

The program for the week is as follows:

October 20. The Dining Worrier.
October 21. Keeping Books.
October 25. Leisure — What Do You Do with It?

Five minute health talks may be heard over the Columbia Broadcasting System daily except Sundays and holidays, from 12 to 12:05 p. m.

The program for the week is as follows:

October 20. Too Much Speed.
October 21. School Days Should Be Health Days.
October 22. Awakening Dormant Health and Happiness.
October 23. If I Were 21 Again.
October 24. Fashion and Motherhood.
October 25. Wardrobe for the Well-Dressed Baby.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

CALIFORNIA

Hospitalization by the University.—The director of the University of California Hospital reports that the outpatient department of the medical school gave care in 1929-1930 to 53,827 women, 57,112 men, 19,321 children and 3,700 infants, and gave free hospital service, including medical treatment or operations, to 1,426 persons who were unable to pay for an average of two weeks' hospitalization. During the fifteen years the sum of treatments for the benefit of the public health in California has just about tripled.

Society News.—The San Diego County Medical Society was addressed, October 14, by Dr. Lyell C. Kinney on "The County Medical Society — A Business Organization."——Dr. John H. Stokes, professor of dermatology and syphilology, University of Pennsylvania School of Medicine, Philadelphia, gave four lectures before the San Diego Academy of Medicine, September 16-19, on "Current Knowledge and Progress in Syphilology."——The Alameda County Medical Society and the San Francisco County Medical Society will meet jointly, October 20, at Oakland; the speakers will be, among others, Drs. Harold Brunn and Bernard Kaufman on "Surgical Pneumonias: Mistakes in Diagnosis and Treatment" and "Precordial Pain," respectively.——A symposium on right-sided lower abdominal pain was held before the San Francisco County Medical Society, October 14, the speakers being Drs. Allan L. Cohn, LeRoy Brooks and Franklin I. Harris.

GEORGIA

Society News.—The Fulton County Medical Society was addressed, October 2, by Dr. Charles B. Upshaw on "Conservative Treatment of Eclampsia," and Dr. W. Frank Wells on "Sociologic Phase of the Medical Profession."——The Richmond County Medical Society was addressed at Augusta, August 21, by Dr. Haven Emerson, New York, on "Periodic Health Examinations."

ILLINOIS

Hearing Tests for School Children.—Arrangements have been made by the Illinois State School for the Deaf, Jacksonville, to provide an experienced staff with audiometer equipment to make free hearing tests of school children wherever desired. The purpose of the service offered is to locate children having hearing defects with a view to promoting treatment when advisable and on recommending suitable modification of teaching facilities when it is necessary. In Illinois more than 200,000 children of school age have defective hearing. Requests for the service should be filed with the state department of public health at Springfield or with the school management at Jacksonville.

Society News.—Dr. Harry M. Hedge, Chicago, addressed the Rock Island County Medical Society, October 14, on "Modern Conceptions and Treatment of Syphilis."——Dr. Isador S. Trostler, Chicago, addressed the McLean County Medical Society at Bloomington, October 14, on "Roentgenotherapy of Conditions Other Than Cancer."——The county medical societies of Crawford, Lawrence, Richland and Wabash were addressed at a joint meeting, September 25, by Drs. Herbert N. Rafferty, Robinson, on "Kidney and Ureteral Stones"; Wendell I. Green, Lawrenceville, "The Use of Glucose," and George T. Weber, Olney, "Medical Disasters."——"Dermatology and Its Relation to General Medicine" was the subject of Dr. Max S. Wien, Chicago, before the Fulton County Medical Society, September 17.——The McDonough County Medical Society was addressed, October 14, by Drs. James G. Carr, Jr., and William C. Danforth, Northwestern University Medical School, Chicago, on "Management of Pregnancy Complicated by Heart Disease."

Chicago

Society News.—A joint meeting of the Chicago Council of Medical Women and the Chicago Medical Society will be addressed, October 29, by Dr. Bertha Van Hoosen on eclampsia which will include a motion picture and a preliminary report of research on colostrum in the eclamptic patient; Dr. Mabel E. Gardner, Cincinnati, will speak on "Multiple Small Peritoneal Cysts of the Fallopian Tubes,." and Dr. Susan R. Offutt, Rochester, Minn, "Chronic Cervicitis."

Nursing for Families of Moderate Means.—The hourly nursing service of Chicago, sponsored by the Joint Committee on Hourly Nursing, has received from the Julius Rosenwald Foundation financial assistance that will cover all of the promotional expenses and one half of the operating expenses of this organization. This service was initiated by the joint committee representing the Central Council for Nursing Education and the First District Illinois State Association of Graduate Nurses in order to bring the best nursing service within the reach of people of moderate means and to furnish nursing by appointment where full-time nursing service is not needed.

INDIANA

Society News.—Dr. George S. Bond, Indianapolis, talked on "Hearts and Heart Sounds" before the Jay County Medical Society at Portland, October 3.——A two-day school for physicians was conducted, October 2, under the auspices of the public health board of Evansville, to which members of the Vanderburgh County Medical Society were invited. Among the speakers were Drs. Carl A. Hedblom, Chicago, on "What Surgery Has to Offer in the Treatment of Pulmonary Tuberculosis"; Charles B. McGlumphy, "Pathology of Pulmonary Tuberculosis"; Gardner C. Johnson, Evansville, "Laboratory Aids"; Paul D. Crimm, "Rôle of the Montoux and X-Ray Findings in Childhood Tuberculosis," and Herman M. Baker, "Nontuberculous Diseases of the Lung."

State Medical Election.—At the annual meeting of the Indiana State Medical Association, September 25, Dr. Alois B. Graham, Indianapolis, was made president; Dr. Franklin S. Crockett, Lafayette, president-elect, and Mr. Thomas A. Hendricks, Indianapolis, reelected secretary. The next annual meeting of the association will be held in Indianapolis, Sept. 23-25, 1931. Among other actions taken by the house of delegates was the adoption of the report of the laboratory men and the Indiana State Board of Health in regard to eliminating free laboratory service by the state board for those who are able to pay; the rejection of a full-time health officer resolution, and approval of the work done by the fact finding committee appointed by Governor Leslie to survey the tuberculosis situation in Indiana in view of determining the best possible locations in the state for sanatoriums for the treatment of this disease. The organization of the Woman's Section of the Indiana State Medical Association was perfected at a meeting of women physicians of the state held following a banquet in their honor. The president is Dr. Nettie B. Powell, Marion; Dr. Kathryn M. Whitten, Fort Wayne, vice president, and Dr. Bonnell M. Souder, Auburn, secretary.

LOUISIANA

Dr. Lewis Celebrates Ninetieth Birthday.—Dr. Ernest S. Lewis, emeritus professor of obstetrics and gynecology at Tulane, was guest of honor at a luncheon, September 24, given by medical colleagues celebrating his ninetieth birthday. Dr. Lewis has been connected with Tulane University for sixty years. He has served as president of the Southern Surgical Association and was elected in 1929 a life member of the Louisiana State Medical Society for his contributions to medical science. The speaker was Dr. Rudolph Matas.

MARYLAND

Courses on Diagnosis of Cancer.—Graduate courses for surgeons and radiologists, held four times a year at the Johns Hopkins Hospital, Baltimore, were announced at the recent three day graduate teaching course on "The Diagnosis and Treatment of Bone Tumors," held under the auspices of the Garvan Research Laboratories and the Copely Surgical Pathological Laboratory of Johns Hopkins University, under the direction of Dr. Joseph Colt Bloodgood. The attendance comprised 363 physicians from 42 states. The plan is to supplement the new courses by correspondence and a system of diagnosis in which roentgen plates are sent in by nonresident radiologists. Another development announced in the war on cancer is the creation of a corporation to advance the science of radiology as it bears on the diagnosis and treatment of cancer. This corporation—the Radiological Research Institute—will finance research workers and fellowships in universities and is made possible by gifts from the Chemical Foundation and its president, Francis P. Garvan. The graduate course given at Johns Hopkins will be repeated before the meeting of the Radiological Society of North America in Los Angeles, December 1-5; the admission is free, but attendance is limited to 800.

Personal.—Dr. Christian Deetjen submitted to the amputation of his left arm at the elbow, October 1, at Mercy Hospital. Dr. Deetjen has been a pioneer in the use of roentgen ray for thirty years. The operation, the eighth which he has had on his arm, is the result of his activities in this branch of medicine.——Dr. John Rathbone Oliver, for fifteen years chief medical officer of the supreme bench of Baltimore, officially ended his court service, September 30. He will assume the chair of assistant professor of the history of medicine at Johns Hopkins University School of Medicine.——John C. Krantz, Jr., Ph.D., has been appointed chief of the bureau of chemistry, state department of health, to fill the vacancy created by the death of Wyatt W. Randall, Ph.D.——Dr. William S. Keister, formerly health officer of Prince Georges County and secretary of the county medical society, has been appointed assistant health officer of Baltimore County.——Drs. Leo V. and Rebecka S. Schneider were recently appointed health examiners of the Playground Athletic League of Baltimore after having spent five years as resident physicians of the Maryland Tuberculosis Sanatorium.——Dr. Gordon Morgan Holmes, London, England, addressed the neuropsychiatric section of the Baltimore City Medical Society, October 8, on "Some Reflexes." Dr. Holmes will spend a month in Baltimore as visiting lecturer in neurology at the Johns Hopkins University School of Medicine. He is physician to the National Hospital for the Paralysed and Epileptic and to Charing Cross Hospital, London, and is also editor of *Brain*.

MASSACHUSETTS

Personal.—Dr. Alton S. Pope has succeeded Dr. Sumner H. Remick as director of the division of tuberculosis of the state department of public health. Dr. Remick resigned to become superintendent of the Middlesex County Tuberculosis Sanatorium, which is in process of construction at Lexington.——Dr. Harold Edward MacMahon, London, Ontario, has been appointed professor of pathology and bacteriology at Tufts medical and dental schools, Boston.

Society News.—The Middlesex South District Medical Society held a symposium on uterine bleeding, October 16; the speakers were Drs. Alonzo K. Paine, Frederick J. Lynch, Marion F. Eades, Frederick L. Good, Louis E. Phaneuf, Foster S. Kellogg and Samuel R. Meaker, Boston, and Charles E. Mongan, Somerville.——"Recent Advances in the Immunology of Infectious Diseases" was the subject of Dr. Edwin H. Place before the Greater Boston Medical Society, October 7.——The William Harvey Society of the Tufts College Medical School, Boston, has announced a course of eight lectures to be delivered on the second Friday of each month at 8 o'clock in the auditorium of the Beth Israel Hospital. The first lecture was given by Dr. Alfred Worcester, Waltham, October 10, on "The Young Adult Male"; the second will be given, November 14, by Dr. Howard W. Haggard, New Haven, Conn., on "Medicine Through the Ages." The society, which was founded last spring by the students of the medical school, seeks to further interest in the art of medicine. In general, the humanities in their relation to medicine will be emphasized rather than the scientific and technical aspects of the subject.

MICHIGAN

Conferences on Communicable Diseases.—The Detroit Department of Health and the Wayne County Medical Society are offering a series of clinical conferences on acute communicable diseases at the Herman Kiefer Hospital, to begin October 29 and continue each Wednesday morning thereafter. This is the second series which deals with the practical problems in diagnosis and treatment, presented by means of case histories and demonstrations of patients; this series of clinics was initiated for the purpose of aiding the physicians by practical demonstration rather than by didactic instruction.

Northern Michigan Children's Clinic.—Arrangements were recently completed in Marquette between Senator Couzens, trustees of the Children's Fund of Michigan and the trustees of St. Luke's Hospital for the establishment of the Northern Michigan Children's Clinic. This is to be housed in a three story fireproof building to be erected this fall and winter on the grounds of St. Luke's Hospital, and will be operated in conjunction with St. Luke's, for the benefit of upper peninsula children. Assistance for the new clinic has been arranged with the University of Michigan Hospital, which will send specialists in for consultation. In the interim, a round-up of children to be brought to the clinic for expert diagnosis and medical or surgical attention will be conducted by a nurse delegated to each county working under the auspices of the Children's Fund. Senator Couzens met health officials at Houghton, September 21, where tentative plans were made for the installing of the modern health unit in Houghton County, which will be served by a physician, a dentist, and three or more nurses.

MISSISSIPPI

Society News.—The Issaquena-Sharkey-Warren Counties Medical Society was addressed, September 9, by Drs. Street on "Carcinoma of the Large Intestine," illustrated; Willard H. Parsons, "Indications for Biopsy," and Noel C. Womack, Jackson, "Intracranial Hemorrhage in Infants."——"Uterine Hemorrhage" was the subject of Dr. Van Buren Philpot, Houston, before the Northeast Mississippi Thirteen County Medical Society at Corinth, September 16; Drs. James S. McLester, Birmingham, Ala., spoke on the anemias; Matthew J. L. Hoye, Meridian, organized medicine; Felix J. Underwood, Jackson, hospitals, nurses and health, and Hunter L. Scales, Starkville, some remarks on the care of so-called maternity cases.——Dr. S. Paul Klotz, McComb, addressed the Pike County Medical Society, September 4, at McComb on empyema; several motion pictures were shown.——The Tri-County Medical Society was addressed at Tylertown, September 9, by Dr. DeWitt T. Langston, New Hebron, on the relation of spasm of the colon to nervous indigestion.

MISSOURI

Missouri Reestablishes the Clinical Years.—The Board of Curators of the University of Missouri, on recommendation of the Missouri State Medical Society and the faculty of the School of Medicine, has authorized the reestablishment of the clinical years in the medical school. While the University of Missouri in 1909 discontinued the two years of clinical work in the medical school, it now seems possible to begin again the teaching of clinical medicine. An outpatient clinic was recently established by the University Hospitals, and cooperation with the Boone County Hospital, with the University Hospitals and possibly with other hospitals will provide a teaching unit. In September, 1931, as many of the present sophomore class as the clinical facilities accommodate will be admitted to the new third year curriculum in the medical school; in the fall of 1932 the senior courses will be inaugurated, and in 1933 the degree of Doctor of Medicine will be granted to students who satisfactorily complete the curriculum. The board of curators for the present will expand the medical school as rapidly as the state and university finances permit. As a two year school, it has been rated class A by the American Medical Association. The University of Missouri is well situated to train practitioners at a low cost to students who probably will remain in the state to practice; it has trained many of the physicians who at present practice in Missouri. The university first provided medical education in 1845, when the medical department was known as the Missouri Medical College in St. Louis. During the Civil War and until 1872 the medical school was discontinued. Then it was reopened at Columbia and in 1891 the medical course was extended to three years, and in 1899 to four years. Following the standardization of medical education inaugurated by the American Medical Association, the board of curators in 1909 discontinued the clinical work because of its cost and the lack of clinical material. For twenty-one years the school of medicine has offered only courses preliminary to the clinical work. During that time the school has rated high as a teaching and research institution. It will be the aim of the school authorities to keep the school in the front ranks with the reestablishment of the clinical years of instruction.

NEVADA

State Medical Meeting and Election. — The twenty-seventh annual meeting of the Nevada State Medical Association was held at Reno, September 26-27. Papers were presented by Drs. George R. Magee, Yerington, on "Relapsing Fever"; Stanley H. Mentzer, San Francisco, "New Methods in the Technic of Cholecystectomy"; Louis I. Breitstein, San Francisco, "Breech Delivery" (with moving pictures); Ralph A. Bowdle, East Ely, "Spinal Anesthesia"; De Los Schuyler Pulford, Jr., Woodland, Calif., "Benzol Poisoning: A Report of a Case Simulating Anemia and Hemorrhagic Purpura"; Benjamin Jablons, New York, "Hypertension"; Edward Matzger, San Francisco, "Seasonal Hay-Fever and Seasonal Asthma —A Preventable Disease," and Claude F. Dixon, Rochester, Minn., "Clinical and Surgical Aspects of Diseases of the Biliary Tract"; James T. Watkins, San Francisco, "Treatment of Severe Flexion Deformities of Hip and Knee Following Neglected Infantile Paralysis." Dr. Robert P. Roantree, Elko, was installed as president of the association, September 26; Dr. Amos C. Olmsted, Wells, was made president-elect, and Dr. Horace J. Brown, Reno, reelected secretary. The next annual session will be held at Ely in September.

NEW YORK

Conference Outlines Plans of State Society. — The executive committee of the state medical society formulated plans at a conference called by President William H. Ross, Brentwood, September 11. Activities in medical education will include a continuation of courses in graduate education, of which eight courses have been arranged to be given before county medical societies; the experiment of a postgraduate clinic day has been arranged at Glens Falls, Washington County, to be conducted by a teaching team from Syracuse University. Medical education will be furthered by short articles in the state medical journal and will show how preventive medicine can be practiced on a person who comes to get treatment for a specific condition. Public health activities are to include a survey of each county to ascertain what form of medical service is needed and to promote it. Other activities include a stimulation of the practice of more preventive medicine by the family physician, better tuberculosis control, active anticancer work and a collection of news of the activities of other sources. The public relations committee will aim to establish free relations with all agencies working in the field of health or curative medicine; it will aid in the development of hospitals by counties, promote public health, and make surveys of every county and a study of medical services and health work among the students and colleges of the state. In an effort to educate people who seek and physicians who give periodic health examinations, the committee plans to do educational work through lay organizations and to stimulate physicians personally in making examinations. Education is also the key note of the work of the physical therapy committee, which plans to send lecturers to medical societies, make surveys of hospitals, and promote the employment of heads of physical therapy departments. It will sponsor training courses for technicians and graduate courses for physicians, promote instruction among medical students, and arrange for physical therapy for workmen's compensation cases.

New York City

Society News.—Dr. Theobald Smith of the Rockefeller Institute for Medical Research, Princeton, N. J., delivered the William Henry Welch Lectures under the auspices of the trustees and medical staff of the Mount Sinai Hospital on "The General Problem of Respiratory Diseases as Illumined by Comparative Data" and "A Comparative Study of Spontaneous and Induced Streptococcus Disease in the Same Species," October 17 and 18, respectively.

Information Service Formed.—The city health department recently inaugurated a tuberculosis information and advisory service as an adjunct to the four diagnostic chest stations operating in the city. The purpose is to curb tuberculosis by further assistance to the family physician in cases in which a patient suspected of having tuberculosis can be sent for a complete diagnostic examination, including roentgen examination available without cost. The service is open to any person believing himself to be suffering from tuberculosis of the lungs. He can get a complete history and if his condition warrants it he will be urged to call on his family physician, who will have him sent to the diagnostic chest station. If the physician decides that the patient should be sent to a sanatorium, he will be referred to the advisory service. So far as known there are about 25,000 known cases of tuberculosis in the city. The prime purpose of this service is to reach each of these tuberculosis contacts in order to check materially the spread of the disease and eventually eradicate it.

NORTH CAROLINA

Personal. — Dr. Clem Ham, director of the Pitt County Health Department, has resigned; he will be succeeded by Dr. Robert S. McGeachy of Lenoir County.——Dr. Frank M. Register, Raleigh, after having been connected with the state board of health for sixteen years, has resigned and become health officer of Wayne County.

Dr. Jacocks Appointed State Health Officer.—Dr. William P. Jacocks, formerly of Windsor, but for the last fifteen years with the International Health Board and for the last ten years in charge of the health work of the Rockefeller Foundation in India with headquarters at Ceylon, has been elected state health officer of North Carolina by the state board of health. Dr. Jacocks succeeds Dr. Charles O'H. Laughinghouse, recently deceased.

Society News. — "Postencephalitic Psychiatric Problems" was the subject, among others, of Dr. Olin B. Chamberlain, Charleston, before the Greenville County Medical Society, October 6.——The Ninth District Medical Society was addressed, September 25, at Salisbury by Drs. John S. Norman, Hickory, on "Mastoiditis"; David S. Asbill, Statesville, "Some Observations on Bronchoscopy"; Oscar B. Darden, Richmond, Va., "Masked Pellagra"; Charles W. Armstrong, Salisbury, "Home Treatment of Tuberculous Children"; Walter F. Cole, Greensboro, "Fractures of the Shaft of Long Bones"; Frank Howard Richardson, Brooklyn, "Some Emotional Problems of Childhood"; James K. Hall, Richmond, Va., "The Physician as Community Counselor," and John T. Burrus, High Point, "Importance of Organized Medicine." The society voted to ask the legislature to repeal the $25 annual license tax which physicians in North Carolina must now pay; they further requested that the statute of limitation for bringing against physicians alleged malpractice be made one year instead of three.

OHIO

Society News.—At the annual meeting of the Northwestern Ohio Medical Association, Toledo, October 7, the program consisted of papers by Drs. John Alexander, Ann Arbor, Mich., on "Present Status of Thoracic Surgery"; Ferris Smith, Grand Rapids, Mich., "Asthma—Its Etiology and Cure"; Ralph Pemberton, Philadelphia, "Arthritis"; Irvin W. Potter, Buffalo, "Abdominal Cesarean Section"; Charles P. Emerson, Indianapolis, "Functional Neuroses Which the Internist Sees"; William C. Quinby, Boston, "Urinary Lithiasia"; Frederick A. Coller, Ann Arbor, "Carcinoma of the Stomach"; Donald C. Balfour, Rochester, Minn., "Recent Developments in the Management of Lesions of the Stomach and Duodenum"; Chester W. Waggoner, Toledo, president, state medical association, "The Importance of the Practice of Medicine to Community," and Mr. Grove Patterson, editor, Toledo *Blade*, "Editors and Folks."——The Warren County Medical Society was addressed at Lebanon, September 2, by Dr. John E. Witham, Waynesville, on "Spinal Meningitis."——Dr. John T. Quirk, Piqua, addressed the Miami County Medical Society at Troy, September 5, on "Diagnosis and Treatment of Pernicious Anemia."——The Shelby County Medical Society was addressed, September 5, at Sidney, by Dr. Benjamin A. Stephenson on infant mortality.——Dr. William B. Hubbell, Elyria, addressed the September 9 meeting of the Lorain County Medical Society on periodic health examinations.——Dr. Robert B. Drury, Columbus, addressed the Perry County Medical Society at New Lexington, September 15, on prostatectomy.——"Oral Surgery, Its Relationship to Physician and Dentist" was the subject of Dr. Hugh W. MacMillan, Cincinnati, before a joint meeting of the Muskingum County Academy of Medicine and the Muskingum Valley Dental Association, September 10.

PENNSYLVANIA

Society News.—The Fayette County Medical Society was addressed, October 2, by Dr. Lester Hollander, Pittsburgh, on "Eczema and Ringworm."——The Montgomery County Medical Society conducted a symposium on mental hygiene, October 1, at Norristown; the speakers were Drs. Frederic H. Leavitt, Joseph McIver and Charles W. Burr, Philadelphia.——The

Washington County Medical Society was addressed, October 15, by Dr. Robert A. Knox, Washington, on "Hypertrophic Stenosis of the Pylorus."

Grant for Study of Cellular Reactions.—The Rockefeller Foundation has announced a $75,000 grant to the University of Pennsylvania for the extension of the method of studying the microscopic details of the growth of living tissues in warm blooded animals. The money is to be paid in instalments of $15,000 a year for five years. The method that has been developed in the department of anatomy consists of the introduction of a transparent double wall chamber or window into a small hole made in the ear of a rabbit. One side of this window is covered with celluloid or glass and the other with a thin sheet of mica. The intervening space is left in contact with the tissues of the ear and from them blood vessels and other living tissues invade the chamber until they form a new layer. This layer is transparent and can be studied microscopically in situ; through its use abnormal cellular reactions and living tissue can be ascertained. Moving pictures of the circulation of the blood in these chambers have been taken. The window method was demonstrated at the recent celebration of medical progress held at the university.

Philadelphia

Personal.—Dr. Virgil Holland Moon delivered the address introductory to the one hundred and sixth annual session of the Jefferson Medical College, September 22, on "Pathology in Relation to Human Life."——Dr. Chevalier Jackson has accepted invitations to give a series of lectures and demonstrations at the St. Louis Hospital, Paris, and the Royal Society of Medicine, London.

Hospital News.—A new building in which fifty tuberculous prisoners may be treated separately was opened, October 1, at the Holmesburg Prison. The cost was $150,000.——The endowment of a free bed in the Germantown Dispensary and Hospital for the use of teachers and other employees of the Philadelphia public school system was provided in the will of Oliver P. Cornman, Ph.D., educator, who died in the hospital, September 6.

University Appointments.—The following appointments at the University of Pennsylvania Medical School, among others, were recently announced: Dr. Earl D. Bond, professor of psychiatry; Dr. Kenneth E. Appel, assistant professor of psychiatry; Dr. Frederick H. Allen, assistant professor of psychiatry. In the Graduate School of Medicine, Dr. Francis W. Sinkler has been appointed professor of neurology; Dr. Leon Herman, associate professor of urology; Dr. Henry F. Page, associate professor of medicine, and Dr. Edward L. Bortz, assistant professor of medicine.

Award of the Next Alvarenga Prize.—The College of Physicians of Philadelphia has awarded the Alvarenga Prize for 1930 to Dr. Henry A. Harris, London, England, for his essay entitled "Cod Liver Oil and the Vitamins in Relation to Bone Growth and Rickets." The next award of the prize will be made, July 14, 1931. The essay intended for competition may be on any subject in medicine but it must not have appeared previously in print nor presented elsewhere in competition for a prize. The essay should represent an addition to the knowledge and understanding of the subject based either on original or on literary research. Each essay must be sent without signature but must be plainly marked with a motto and be accompanied by a sealed envelop having on its outside the motto of the paper and within the name and address of the author. It must be received by the secretary of the college, 19 South Twenty-Second Street, Philadelphia, on or before May 1, 1931. The prize amounts to about $300, being the income for one year from the bequest of the late Senor Alvarenga.

VIRGINIA

Society News.—The Loudoun County Medical Society was addressed, September 9, at Purcellville, by Drs. Walter A. Bloedorn, Washington, D. C., on "New Cardiac Aspects and New Cardiac Therapeusis," and John C. Eckhardt, Washington, D. C., on "Cod Liver Oil: Its Vitamins and Those of Some Other Foods."

The Pellagra Situation.—In view of the general prevalence of pellagra throughout the south, Virginia showed between 1915 and 1924 a decreasing death rate from this disease. Since 1924, however, the death rate in Virginia has risen year by year. There were seventy-five deaths from pellagra in 1924 and 227 in 1929, 16 more deaths than there were from diphtheria and 103 more deaths than there were from typhoid.

State Medical Meeting at Norfolk, October 21-23.—The sixty-first annual session of the Medical Society of Virginia will be held at Norfolk, October 21-23, under the presidency of Dr. Charles R. Grandy, Norfolk, and with headquarters at the Monticello Hotel. The program will include papers by Drs. David R. Lyman, New Haven, Conn., and William S. Thayer, Baltimore (subjects not announced); John Shelton Horsley, Richmond, "Cancer of the Stomach, with Special Reference to Its Incidence, Diagnosis and Treatment"; Claude Moore, Washington, D. C., "Value of the Roentgen Ray in Diagnosis of Lesions of the Colon"; James Edwin Wood, Jr., University, "Significance of Blood Pressure Changes in Hypertension"; Douglas G. Chapman, Richmond, "Thyroid Extract in Treatment of Certain Cardiac Diseases"; William B. McIlwaine III, Petersburg, "Congenital Hypertrophic Stenosis of the Pylorus"; Edgar M. McPeak, Washington, D. C., "Treatment of Carcinoma of Cervix by Radium and X-Ray"; Frank S. Johns, Richmond, "Important Developments in Thoracic Surgery"; Robert Finley Gayle, Jr., Richmond, "Management of the Psychoneurotic"; Staige D. Blackford, University, "Differential Diagnosis of Tularemia"; William B. Huff, Roanoke, "Torsion of the Omentum Presenting Symptoms and Signs of Acute Appendicitis," and Charles P. Cake, Detroit, "Phrenicotomy in the Treatment of Suppurative Pulmonary Disease." A symposium on syphilis will be conducted, Wednesday. The Virginia Pediatric Society and the Alumni Association of the Medical College of Virginia will hold their annual luncheons at this time at the Southland Hotel, and the Virginia Roentgen Ray Society will be the guest of Dr. James W. Hunter, Jr., at the Monticello Hotel. A golf tournament will be held, Tuesday, at the Norfolk Country Club.

WASHINGTON

State Medical Election.—At the annual meeting of the Washington State Medical Association, September 3, Dr. Arvid E. Anderson, Aberdeen, was elected president, and Dr. Curtis H. Thomson, Seattle, was reelected secretary. The next annual session will be held at Aberdeen.

GENERAL

Chamber of Commerce Health Contest.—The U. S. Chamber of Commerce has announced its 1930 interchamber health conservation contest. The object is to assist in reducing economic losses in the United States due to unnecessary illness and death by organizing health committees of local chambers of commerce or similar associations which will assume leadership in cooperating with the official and voluntary health agencies of the community. To stimulate endeavor, recognition will be given the many communities which have been active in the past as well as those which will undertake work of this nature in the future. Each chamber submitting information will have the health conservation work of its city carefully scored. Cities are rated according to their population. Printed schedules covering the items on which the chambers are to be graded must reach the chamber of commerce, Washington, D. C., as soon as possible after the close of 1930. No schedule will be accepted for grading after March 1, 1931. The board of judges consists of the grading committee and the chairman and representatives of the insurance committee of the U. S. Chamber of Commerce.

Report on Supply of Nurses.—The nursing situation was recently investigated by the Committee on the Grading of Nursing Schools, which sent out questionnaires on the demand for nurses in the practice of 4,000 physicians. Of the patients who did not have a special nurse recommended as necessary, it was found that 45 per cent could not afford a nurse; 29 per cent were cared for by relatives and friends; 13 per cent did not want a nurse; 7 per cent were cared for by a visiting nurse, and 6 per cent of these patients, or 2 per cent of the total number, wanted a nurse but could not find one. More than 500 patients who did not want a nurse and did not engage one were, in the opinion of their physicians, in need of skilled nursing care. Twenty-six per cent of the physicians felt that some of their patients could have been cared for by a visiting nurse or hourly nursing service, and 27 per cent felt that the service of relatives or competent servants would have been adequate. Seventy-three per cent of the physicians stated that it is harder for the patient to pay the nurse's fee than to obtain her services. Of 23,500 general practitioners answering concerning the general need for private duty nurses in their practice, 87 per cent said they needed them often, 5 per cent occasionally, and 8 per cent practically never. Twenty per cent of these physicians got their nurses through their own list, while 17 per cent secured them through central registries, 15 per cent from commercial registries, and 5 per cent from unspecified sources.

Nullify Law for Preventing Precocious Maternity in India

In previous letters, medical aspects of the Indian situation have been dealt with. The latest census, according to the invaluable report of the Simon commission, shows an excess of 9 million males over females and the gap, which is widest at the ages from 10 to 20, appears to be connected with customs such as purdah, early marriage and unskilful midwifery, which are detrimental to the females. The census shows that 2 million were married before the age of 10. April 1 the Sarda act, which prohibits the marriage of girls under 14 or boys under 18, came nominally into force. It was stated (THE JOURNAL, July 12, p. 137) that, "if adequately observed," it should prove beneficial physically and mentally to women. Unfortunately the condition has proved necessary. In a letter to the *Times*, Miss E. F. Rathbone, member of parliament for the Combined English Universities, a philanthropist and a writer on political and economic subjects, and the leader of the women's movement in this country, points out that one tragic result of Indian politics is that the Sarda act has not been enforced. The council of state has circulated for the opinion of provincial governments a proposal which virtually nullifies the act by permitting exemptions on grounds of "conscientious objection" or "peculiar family reasons"—grounds which between them cover every possible child marriage. The reason for this reactionary proposal is partly that the congress party, which clamored for the act and bitterly reproached the government for its slowness in passing it, is now using it to stir up the orthodox by representing it as the first fruits of a policy of interfering with religious customs: partly that the Moslems are demanding its abrogation as part payment of their loyalty to the government. Miss Rathbone's first reaction to this failure of the government to enforce the act was to consider it guilty of cowardice and cruelty. But none of the many experts on Indian affairs whom she consulted would agree with her. They thought that so long as the reforming and emancipated section of Indians, both men and women, are wholly absorbed in the political struggle and willing to use any weapon to stir up the orthodox against the government, the difficulties and dangers of enforcing this and other social reforms are too great.

The evil, which the tactics of Indian politicans is perpetuating, is revealed in the exhaustive report of a government committee consisting of nine Indians and one British physician. It estimates that nearly half the girls of India are married before 15, that marriages are consummated not infrequently before but usually soon after puberty, and that this custom is diminishing at an exceedingly slow pace. The report declares that early maternity contributes largely to maternal and infantile mortality, in many cases wrecks the physical system of the girl, and generally leads to degeneracy of the race. It points out that Sati (immolation of a Hindu widow on her husband's funeral pyre), which the British government stopped, was rare, but premature maternity is widespread among Hindus and Moslems. If a woman survives the ordeal she is old at 30, a shadow of her former self. "Her life is a long lingering misery and she is a sacrifice on the altar of custom. If legislation was justified for preventing Sati there is ample justification for preventing early maternity both on the grounds of humanity and in furtherance of social justice." Experts estimate the maternal deaths as 15 per thousand confinements and some think that this estimate is far too moderate. Yet reforming Indians, convinced of the enormity of the custom, nullify the law passed to abrogate it and at the same time try to represent themselves to the western world as victims of British tyranny. Before such pretension they should show more consideration for their own women as well as for the pariahs, amounting to 60 millions, who are kept degraded by Hindu custom and whose emancipation, so far, is entirely the work of the British government.

Report of Ministry of Health: Malingering Due to Medical Socialism

The annual report of the ministry of health shows that there are 14,000 physicians on the panel and that the number of insured persons entitled to medical benefit was a little over 14,000,000. Medical benefit cost $43,000,000. Of this the panel physicians received $31,200,000 for attending the insured. The malingering which this system of medical socialism promotes was described in a previous letter (THE JOURNAL, September 6, p. 738). Further proof of its magnitude is shown by the following: As the ordinary panel physician cannot prevent malingering, "regional medical officers" are appointed to whom can be referred cases in which doubts have been raised as to the incapacity certified by the panel physician. This can be done by the societies, by the panel physicians or by the insurance committees. The number of cases referred to the regional medical officers for advice as to incapacity for work was 410,903. But the prospect of examination caused 109,661 persons to "declare off the funds" and thus avoid examination, and 89,750 failed to attend "for other reasons." Thus the number actually examined was reduced to 143,898. Of these, 76,162 were reported as incapable and 67,736 as capable of work. Thus, only just over a third of the claimants of benefit passed the test.

Danger of Wrapping Cheese in Tinfoil

In the report on adulteration of food, a note of warning is sounded with regard to the common practice of wrapping cheese in tinfoil. The analyst found several samples highly contaminated with tin and had no doubt that the person who lodged the complaint that he had been made ill by eating the article was justified. As a result of this disclosure, further samples of wrapped cheese of varying brands were analyzed and in no case were they found free from contamination with tin. The convenient practice of wrapping cheese in tinfoil is therefore declared to be a potential danger and manufacturers are advised to prevent contact between the cheese and the tinfoil by interposing grease-proof paper or other means.

Iodine in Prophylaxis of Goiter

In his Cavendish lecture to the West London Medico-Chirurgical Society, Professor de Quervain of Berne discussed, from his vast experience, goiter and cretinism. Regarding the prophylaxis of goiter by administration of iodine, he pointed out that a daily dose of 0.5 mg. is sufficient to produce in the adult subjects of goiter a clinical picture resembling hyperthyroidism. Therefore if prophylaxis against goiter is to be harmless the dose must be much lower and must be kept within the limits of the physiologic intake of iodine. It must not exceed 1/20 mg. daily. Yet the dose used in the United States added to table salt is forty times this. The professor did not commit himself to any statement as to whether Americans could take this dose with impunity but said that it would be dangerous in Switzerland.

Sterilization of Mental Defectives

The sterilization of mental defectives is still a topic in the press. In THE JOURNAL, Aug. 23, p. 605, a bill about to be drafted by the Eugenics Society authorizing the sterilization of a mental defective, subject to the consent of the parent or guardian and the lunacy authority, was described. In a letter to the *Times*, Prof. Julian Huxley supports the proposal by showing that the law on sterilization is chaotic, if the operation is performed for any other purpose than the improvement of the individual's health. It appears to be possible that if a man had himself sterilized to prevent transmission of some grave hereditary taint, both he and the surgeon who performed the operation might be subject to a legal penalty. The law is so obscure that most surgeons would not take the risk. Though the committee of the Eugenics Society is aware that insanity does not present the same straightforward problem as regards inheritance as does mental defectiveness, it has inserted a clause legalizing voluntary sterilization in any one afraid of transmitting hereditary defect. At present this is virtually impossible. There are numerous cases of insanity running in families. A sufferer who has married before the onset of his complaint may during his spells of mental health be anxious to be relieved of the fear of procreation. But the committee has no thought of trying to force sterilization on insane persons or on any one with a heritable defect.

PARIS

(From Our Regular Correspondent)

Sept. 24, 1930.

The Epidemic of Poliomyelitis

The epidemic of poliomyelitis, which has lasted for three months, is dying out. There are at present only a few isolated cases. The epidemic started in the vicinity of Strasbourg, which remained its chief center and furnished the largest number of cases (293). From Strasbourg it extended toward the north to Moselle (sixty-seven cases) and to the south to Belfort, by way of Mulhouse. The points attacked formed gradually an incomplete circle about Paris, which was not directly affected. The most distant points reached were Normandy on the west and Châlon-sur-Saône on the south. The epidemic has died out completely in Alsace. The complete history of this epidemic cannot yet be written as the authorities were cautious about giving out information during the summer vacation period for fear of awakening undue anxiety in the minds of travelers and tourists. No document has been published as yet containing the list of localities infected, the number of cases and the number of deaths—not even the documents communicated to the commission of the League of Nations, which gave exact information in regard to cases observed in Switzerland, Austria, Germany, Sweden, Belgium and the Netherlands. As to France, they refer only to Alsace and to Lorraine, as if the epidemic had been confined to these two regions. The newspapers, however, contained many references to small areas of infection outside those regions. All that is known is that the epidemic has been widespread and fairly severe. Some cases were fatal within forty-eight hours. The disease attacked an unusually large number of persons beyond the age of childhood. Several soldiers between 20 and 25 years of age contracted the disease, and the cases in older persons were always severe. The mode of propagation remains an enigma. It has happened that cases have developed in villages located 100 kilometers (62 miles) from the nearest village infected, and without there having been any inhabitants transported from the latter to the former. In new areas of infection, one sometimes observed two or three cases appearing almost simultaneously, without any further cases succeeding. The report of Professor Levaditi and Dr. Jules Renault, who were delegated by the minister of health to follow the march of the epidemic, is eagerly awaited. The antipoliomyelitic serum of Prof. August Pettit has proved exceedingly effective whenever it has proved possible to procure a sufficient quantity and to use it from the beginning of the disease. Calls of physicians in isolated villages for supplies of the serum were often broadcast over the radio.

Ceremonies in Honor of a Predecessor of Pasteur

A group of physicians of the region about Pau (Basses-Pyrénées) celebrated recently, in that city, the memory of their compatriot Dr. Duboué and had affixed to his home a tablet setting forth the stages of his career. The ceremonies were presided over by Dr. Doléris, member of the Academy of Medicine and a native of this region. He recalled that Duboué, in addition to his research on typhoid and cholera, had been the first to discover that the virus of rabies finds its way from the initial wound to the brain by way of the nerves and not through the blood stream. His work was published in 1879. It was two years later that Pasteur read to the academy his own work on rabies, in which he recognized the priority of Duboué.

Cancer and the Endocrine Glands

Among the countless theories in explanation of the origin of cancer, one puts forward the inhibitive and the stimulative action of the endocrine glands on the proliferation of cells that characterize the neoplasm. Arloing, Josserand and Charechon of Lyons have announced an observation that may throw light on certain phases of the problem. They injected into the rabbit ground elements of cancerous tumors produced experimentally in the mouse. As a result, the suprarenal capsules of the inoculated rabbits became the seat of a cellular superactivity in the cortical layer, which was, however, only temporary. These suprarenal capsules during this period became capable of arresting the development of neoplasms in the mouse, when implanted in the tissues of the mouse by grafts or when a glycerin extract is injected under the skin of the mouse. These curious facts have been substantiated by Sokolov, who obtained the same results as the three scientists of Lyons. The latter are endeavoring to apply these laboratory data to man. They have observed that under the influence of fragments of human tumors (pharyngeal and mammary epitheliomas) the suprarenals of the rabbit react still more rapidly than with the epithelioma of the white mouse.

Tuberculosis Among Teachers

The minister of public instruction has decided to strengthen the measures employed to discover tuberculosis among the teachers in all the lycées and colleges, by reason of the danger incurred by the pupils if there are cases of tuberculosis among the teaching or administrative personnel. At present, candidates for positions in these schools are subjected to a medical examination. The minister of public instruction has ordered that, at the end of a year, teachers must submit to a special examination by an expert and sworn phthisiologist, who, if he finds evidence of tuberculosis, may send the teacher or school officer to a sanatorium for treatment. As for teachers living with their families in an educational institution, if a member of their family becomes tuberculous, he must be removed from the institution, and all precautions must be taken to prevent infection spreading among the pupils.

The Prophylactic Institute

The Institut prophylactique, the purpose of which is the prophylaxis and the treatment of venereal diseases, occupies in Paris an immense building on the bank of the Seine and comprises a large number of consultation rooms and laboratories. At its last general assembly, Dr. Arthur Vernes, director of the institute, reported that the number of consultations given in the services last year reached 239,284. From Nov. 1, 1929, to June 30, 1930, the institute recorded 202,000 consultations. The monthly average for last year was 19,940 and in 1930 reached 25,250. New services are to be opened at Brest, Marseilles, Sèvres, Pantin, Bourget and Vert-Galant. A branch of the Institut prophylactique, located in Algiers, has recently been inaugurated by Mr. Pierre Bordes, governor general of Algeria. Through an agreement with the director general of the government railway system, a connection is to be established between the dispensaries of the Institut prophylactique and the medical services of the railway system. In accord with the minister of the colonies, a plan of organization for the crusade against syphilis in the colonies was worked out by Dr. Vernes and approved by the assembly. Dr. Marcel Léger, formerly director of the Pasteur Institute in Dakar, French West Africa, and Dr. Gustave Martin, formerly director of the public health service in Kamerun, will give a special course of instruction for colonial officials: missionaries, administrative officers, directors of factories, and the like. Those who take the course will receive, thus, ideas that will enable them, under medical direction, to participate in the crusade against endemic diseases (smallpox, typhoid, malaria, syphilis, tuberculosis).

The Albert Blum Scholarships

Mr. Albert Blum, president of the Féderation des Alsaciens et Lorrains d'Amériques, has founded six scholarships at the University of Strasbourg and four at the University of Nancy. The latter afford 10,000 francs ($400) for a period of five years and are awarded to a professor of the faculty to enable him to continue his personal researches or studies.

Deaths

Dr. Valude, ophthalmologist, has died, at the age of 72. Since 1890, he had been chief physician of the old and celebrated hospital "Quinze-Vingts," founded in the middle ages by the king St. Louis, and which has always been under the directorship of eminent specialists. He was the author of many works on ophthalmology.

Dr. Léri was an agrégé professor of the Faculté de médecine de Paris and physician to the hôpitaux de Paris. A pupil of Pierre-Marie, he became an anatomopathologist, specializing in studies on the nervous tissues and the bone tissues. He was just under 50 years of age at his death.

ITALY

(From Our Regular Correspondent)

Sept. 15, 1930.

International Congress of Microbiology

The first International Congress of Microbiology, held recently in Paris, was attended by many Italian scientists. The head of the Italian official delegation was Prof. Serafino Belfanti, director of the Istituto sieroterapico in Milan.

Professor Sanarelli of the University of Rome reported the results of his research on the pathogenesis of cholera. The topics discussed by Professor Sanarelli were: intestinal cholera in new-born animals; choleraic peritonitis in guinea-pigs; choleraic algidity. The speaker stated that the normal gastric content of young rabbits constitutes, by reason of its marked acidity, an insurmountable barrier to the vibrios of cholera. When the vibrios come in contact with the buccal mucosa, in order to reach the intestine they have to make a detour. They possess the peculiar property that Sanarelli terms "enterotropism," indicating that their ultimate objective is the intestinal walls, even when they are inoculated into the organism by the subcutaneous, the intravenous or the peritoneal route. Having reached the walls of the intestine by a detour, the vibrios develop their peculiar pathogenic action, which causes the death of the young animals through a toxic process that follows. Speaking of choleraic peritonitis in guinea-pigs, the author, in contrast with what is commonly held in regard to bacterial lysis on the part of the peritoneum, has observed that, on being injected into the peritoneum, vibrios enter the blood stream through the lymph glands and direct their movements toward the stomach and intestine, where they provoke an acute gastro-enteritis. The phenomenon just described Sanarelli terms "gastro-enterotropism." Taking up the topic of choleraic algidity, Sanarelli pointed out that in man cholera is not a simple enteritis, since it may cause algidity. In animals it is characterized by hypothermia and arterial hypotension, asphyctic phenomena, muscular contractures, and anuria. These facts appear as the expression of an anaphylactic phenomenon and are associated with anatomic and humoral changes. There will always be noted, among other things, a considerable desquamation of epithelium of the mucous surfaces, which Sanarelli terms "epithalaxia."

In the discussion, Professor Hahn of Berlin, declared that he shared, to a great extent, the ideas presented.

Professor Bonfanti, in collaboration with Professor Sachs, offered a paper on the significance of lipoids in immunity, giving the results of his own research and of his "school" on various lipoid substances of the organs of mammals, which have spontaneously a hemolytic action. Likewise lipoids of other origin acquire a hemolytic property under the enzymic action of the venom of serpents, bees and wasps. The speaker distinguished different phases of lipoid degeneration in organ extracts, bringing out the results of his observations on the relations existing between the lipoids and the fixation properties of the serum. The importance of lipoids in immunization phenomena and in the pathogenesis of various morbid states is thus fully established.

Professor Vernoni of the University of Rome spoke on undulant fever and epizootic abortion. Professor Carbone of Milan presented a communication on the immunity of plants.

The Death of Professor Pescarolo

The death of Prof. Bellom Pescarolo, of the University of Turin, is announced. Born at Turin in 1861, he was graduated in medicine and surgery in 1885, accepting soon after a post as assistant in the Ospedale di San Giovanni and later in the Clinica medica universitaria in Turin. His researches were carried on in the field of neuropathology, and for that specialty he acquired in 1890 the venia legendi. That year, in *collaboration with Professor Caponotto, he performed* for the first time in Italy the operation for the extirpation of a tumor of the spinal cord. Later, in collaboration with Professor Carle, clinical surgeon of Turin, he furnished a valuable contribution to the surgical studies on the central nervous system. He cultivated also certain branches of medical radiology. In 1923, he established (contributing personally 100,000 lire toward the project) the first Italian center for the study and the treatment of malignant tumors. In recognition of his scientific and his professional services, he received, many years ago, the honorary title of "senator."

Postgraduate Course in Industrial Medicine

The University of Rome, as the result of the recommendation of the Facoltà medica, has decided to organize a postgraduate school in industrial medicine. The director of the school will be, *ex jure*, the president of the Facoltà medica di Roma. The course will occupy two years and will include instruction in the fundamental matters of industrial medicine and general lectures by the directors of the medical clinics and institutes of the university. The courses will be held in the Policlinico del lavoro, which will permit the use of its facilities, including the persons who appear for consultation and treatment. During the first months of activity, more than 6,300 workmen have visited the Policlinico.

Work of Women and Children in Factories

According to recently published statistics, there have been employed in factories, during the current year, 172,615 women and children, in contrast with 147,944 during the previous year. In northern Italy, the majority of the children employed in factories were girls, while in southern Italy and in the islands the majority were boys. In fulfilment of the demographic policy adopted by the government for the protection of the human race, the age limit at which children may first be employed has been continually raised. This year, as compared with last year, there has been a decrease of 3.4 per cent in the number of children 12 years of age and an increase of 1.7 per cent in the number of children between the ages 14 and 15.

In contrast, the number of girls 12 years of age has decreased by 3.1 per cent and the number of girls aged 16 has increased 5.8 per cent.

The Crusade Against Tuberculosis

In accordance with agreements reached with the general management of the public health service, the ministry of war has recently issued new instructions with a view to assuring the application of the necessary prophylactic measures and the institution of medical aid for the conscripts and for military men dismissed from the service because of tuberculosis. The managements of the military hospitals must report to the bureaus of the provincial physicians all the dismissals from the military service on account of tuberculosis, indicating also the precise diagnosis and the particular type encountered, together with a statement as to whether or not the subject was insured against tuberculosis.

Reports on Activities of University Laboratories

The minister of public instruction has ordered that all the directors of university consultation centers, laboratories and institutes shall furnish the minister an annual report on their didactic and scientific activities for the preceding academic year. The report must state the number of class sessions held by the professors. A distinction must be made between scientific researches in course of execution and those that are brought to completion, including publications if any.

VIENNA

(From Our Regular Correspondent)

Sept. 25, 1930.

Congress of League for Sexual Reform

The fourth Congress of the International League for Sexual Reform on a Scientific Basis, held in Vienna, September 17-24, was attended by 650 physicians, psychologists and sociologists from all countries of the world. The chief topics dealt with by the scientific part of the session were: (1) the bad housing situation and sexual reform; (2) sexual stress; (3) sexuality and the inner life; (4) internal secretions; (5) the history of sexual morality; (6) sexuality and the judicial system; (7) birth control and economy of the human species, and (8) the rights of children. Dr. Magnus Hirschfeld of Berlin served as chairman. The inaugural address was delivered by the president, who pointed out that the purpose of the congress was to apply to life itself and to its manifestations the range of modern scientific knowledge that had been gained in regard to the relationships growing out of the sexual life and love between the sexes. The first main topic was discussed by Professor Tandler, head of the health service of the city of Vienna. He emphasized that, along with the need for food, the need of shelter is of paramount importance for the population because it exerts a direct and powerful influence on sexuality and the moral life. The housing situation after the war was bad. In Germany and Austria a family of five members has, on the average, 1.4 living rooms; in France the average is 2.5 and in England 3 rooms. Before the war, 72 per cent of all dwellings in Vienna consisted of 2 rooms, at the most. Such homes sheltered 67 per cent of the inhabitants of Vienna. It goes without saying that the sexual conditions in these small apartments were monstrous. In such crowded quarters, in which children sleep in the same beds with the parents or other adults, there can be no healthy sexual life. Thirty-four per cent of the children with venereal disease, in the Vienna hospitals, became infected through persons who had shared their beds. Hence, sexual reform presupposes a housing reform on a modern basis. Mr. Toller, the communistic writer, presented the subject of sexual stress as affecting criminals living in prisons. The usually strong vitality and sexuality of the persons of both sexes who are inclined toward crime are frequently impaired by forced confinement and directed toward perversions of various types (homosexuality), which habits unfortunately persist after dismissal from prison. Mr. Toller demands that, from time to time, every prisoner, on request, be granted a week's leave of absence for sexual reasons, as is done in Russia.

Dr. Leunbach of Denmark pointed out that the weakminded in institutions usually have weak sexual desires. He approved their sterilization on eugenic grounds; which would make it possible to send them back to their relatives. Frau Dr. Krausfessel of Berlin discussed sexual perversions in children, and presented shocking figures on the frequency of sexual diseases in children and on sexual relations between school children, which are surprisingly frequent in rural regions and offer a wide field for sexual reform in accordance with the suggestions of August Forel.

Particular interest was awakened by the addresses of Frau Dr. Elberskirchen of Berlin and Dr. Wexberg of Vienna, both of whom took the stand that often too great importance is assigned to sexuality with reference to the psychic or inner life of the individual. Both emphasized that the solution of these problems lies in giving children such training as will develop self-control, though, as Professor Winkler of Vienna brought out, some remedies may render good service as sedatives. Similar views were expressed also by Professor Spiess of France, who denied absolutely the far-reaching importance of sexuality for human existence that is ascribed to it, more particularly by Freud and his followers. It is true, sexual desire is a strong, impelling force but only for a few years, as a rule; and it is often subordinate to other instincts.

Dr. B. Schapiro of Berlin discussed the action of the anterior lobe of the hypophysis on the development of the male genitalia. This so-called motor of the sexual function has in recent years (more particularly by the biologists) been brought into the range of scientific research.

An interesting philosophical presentation on the "History of the Growth of Moral Conceptions Pertaining to Sex Life" was offered by the German scientist Rudolph Goldscheid. He showed in an analysis of conditions that the sexual morals of a given period or epoch are conditioned by the desires and the needs of the social class that is dominant at the time.

The conventionists manifested great interest in the address of Geheimrat Dr. Wolf of Berlin on the status of abortion in criminology, which was followed by a discussion on birth control. Professor Wolf brought out that conceptions of right and wrong change from time to time and that theology, jurisprudence and medicine often differ on various points. For example, up to 1869, the Catholic church took a lenient attitude toward abortion, but since 1869 it has shown stern opposition. Plato and Aristotle regarded abortion up to the eightieth day as permissible, while in later periods the church distinguishes two periods, an early period in which the embryo was regarded as not possessing a soul and a later period in which the soul was considered to have entered; hence, abortion during the early period was not punishable. The church came to hold the view that the soul did not enter the embryo until the third month of pregnancy. The present attitude of mankind toward abortion recognizes social reasons for the destruction of the life germ, whether it takes place through prevention of conception or through abortion. Abortion is exceedingly common —much more widespread than would be assumed from the number of court trials for its perpetration. Scarcely 1 per cent of the actual number of cases come before the courts. The prohibition against abortion causes the death in Germany of 6,000 women yearly, owing to abortion carried out in an unprofessional manner by so-called wise women or midwives. The danger is much greater among the lower classes than in the middle and the upper circles of society. For these reasons mankind demands a modification of the existing laws pertaining to the interruption of pregnancy. Prof. Magnus Hirschfeld emphasized that modern laws with reference to the punishableness of homosexuality likewise need modification.

The question of birth control gave rise to an animated discussion. In her paper, Madame A. Popp of Vienna emphasized that contraception is the most important factor in the conscious regulation of posterity. Before the war, the methods of birth control were little known among the lower classes of the population and were not employed to any great extent in the upper classes. Only through the stress of the past fifteen years and the endeavors of many sociologists and physicians has a knowledge of the methods of birth control become widely diffused. In all the larger cities of central Europe, and also in England and in France, there are consultation and instruction centers where women may procure suitable aid in the prevention of conception.

Dr. Norman Haire of London and Dr. Leunbach of Copenhagen discussed the instrumental apparatus and methods employed by them for the prevention of pregnancy; but a number of the physicians present (more particularly, women physicians) opposed these methods as dangerous. The congress was informed that in England a large and active group of physicians is dealing with the problem and that the conservative circles are coming to the aid of the lower classes.

In addition to the presentation of the session papers, there was an instructive exhibit, which dealt with sexual pathology, as revealed in wax models, pictures, apparatus and various preparations. Likewise, a large number of chemical and biologic remedies, hormones and microscopic preparations were shown, so that the visitor could get a clear conception of the progress of the whole movement.

MOSCOW

(From Our Regular Correspondent)

Aug. 11, 1930.

Care of Mothers and Children

The care of mother and child in the Union of Socialist Soviet Republics is effected by a number of institutions of open and of closed type. Their function is educational as well as medical with expectant mothers and children.

An attempt is being made now to disseminate a healthy conception of sexual physiology quite early in the high schools. For this purpose in some schools lectures on sex hygiene are given. The pupils visit the Institute of the Protection of Motherhood and Childhood, where young girls acquire practical information in the care of infants. Analogous educational work is conducted in the marriage registry offices. Here a physician conducts a short discussion with the bride and groom on such subjects as sex hygiene, dangers of abortion, and the symptoms of venereal disease.

The care of pregnant women is carried on in the cities through the "regional consultation" offices (state clinics). These are adequate to the needs and practically all expectant mothers pass through them, receiving medical attention. Here each woman receives instructions as to the hygiene of pregnancy and the essentials of infant care. Discussions and lectures are given and expositions of the Institute of the Protection of Motherhood and Childhood are visited, where diagrams, pictures and specimens illustrating the development of the fetus and the act of labor are shown. Also rational and irrational infant feeding is demonstrated and the fight against antiquated methods is conducted successfully.

At the same time expectant mothers are given medical examination and a routine Wassermann test is performed. Thus the syphilitic are discovered and transferred to special institutions for treatment, which is undertaken before delivery. Social workers follow up the patients, check on the carrying out of the medical advice given, and give further detailed instructions.

The state clinics include a "commission on abortions," which controls the interruption of pregnancy. The legalization of abortion and its performance in well equipped clinics by competent specialists has reduced mortality to a low figure. The state clinic also determines the time for an obligatory cessation of factory work in each individual case and assigns the woman to a maternity hospital. This period of rest embraces about one and one-half to two months before delivery and from one and one-half to two months after; all this time the mother receives her regular salary.

At birth a certain amount of money is paid for buying all the necessary infant equipment and clothing, and a regular allowance is paid for nine months. The maternity hospital receives all the information on file at the state clinic about the course of pregnancy; thus each patient arrives in the maternity ward as a well known, well studied subject. The maternity hospitals again instruct the mother in feeding rules and infant care.

Further care of infants and children is accomplished by the state infant welfare stations, where all the information on file is forwarded from the maternity hospitals. These take care of children up to the third year. Here the babies are weighed and measured regularly and their feeding is controlled. Here also the mothers unable to feed their infants receive a supply from the "milk kitchen" or from the "stations for the accumulation of woman's milk." The latter are institutions where nursing mothers give away the excess of their milk supply under medical control. The social workers see to it that mothers follow the medical advice given. For children over 1 year of age there exist dietetic dining rooms where they receive the proper food.

There are also a number of infant and child stations, the crèche, where mothers working in factories place their children. In accordance with the law, the nursing mother is released from work to feed her baby at the necessary intervals. Of course, there are similar stations for night workers. These infant and child stations are under the control of a physician and specially trained nurses. The infants are there given the proper care, while the older children are educated, particularly along the lines of cooperation, developing the spirit of collectivism. From these stations the children who have reached the proper age are transferred to the kindergartens.

Among the closed institutions, the "houses for homeless mothers" deserve mention. Here the mothers who have just recently delivered and who have no home of their own live for nine months with their babies. These houses are organized as labor communes, as each woman is supposed to do some kind of work.

The "houses for mother and child," another closed institution, provide a home for the mother and the new-born baby for two months. The "house for infants" serves for the raising of foundlings. Likewise children of parents unable to raise them, because of peculiarities in their trade or other conditions, can be placed here in the hands of a medical personnel until they are 1 or 1½ years old. Afterward they are placed in the kindergartens, where they are educated.

Marriages

Edwin Pratt Jordan, Homewood, Ill., to Miss Marjorie Crighton of Brandon, Vt., September 18.

Douglas Doriot Vance, Bristol, Tenn., to Miss Katherine Millner at Norfolk, Va., September 24.

Harvey H. Seiple, Lancaster, Pa., to Miss Elizabeth S. Hostetter of Florin, August 1.

Alexander Marble, Troy, Kan., to Miss Beula Becker in Tremont, Ill., September 20.

Harry S. Fist, Los Angeles, to Miss Beatrice Elise Flesher of Denver, October 4.

Ralph B. Green, Chicago, to Miss Rose Brenner, May 21.

Deaths

James Madison Woodson ⊕ Temple, Texas; Medical Department of the Tulane University of Louisiana, New Orleans, 1891; member of the American Academy of Ophthalmology and Oto-Laryngology, the American Laryngological, Rhinological and Otological Society and the American College of Surgeons; on the staff of the Woodson Eye, Ear, Nose and Throat Hospital; aged 62; died suddenly, September 30, of heart disease.

Leland C. Ellis ⊕ Dallas, Texas; University of Texas School of Medicine, Galveston, 1912; associate professor of clinical surgery, Baylor University College of Medicine; served during the World War; proctologist to the Baylor Hospital and the Parkland Hospital; aged 45; died, August 24, in Carlsbad, N. M., of injuries received in an automobile accident.

Samuel Preston Cunningham ⊕ San Antonio, Texas; Medical Department of the Tulane University of Louisiana, New Orleans, 1898; member of the American College of Surgeons; past president of the Bexar County Medical Society; aged 55; died, August 25, in a local hospital, of carcinoma of the bladder.

Sarah Elizabeth Maule Holland ⊕ Norristown, Pa.; Woman's Medical College of Pennsylvania, Philadelphia, 1925; on the staff of the Montgomery County Hospital; medical inspector for the Norristown schools; aged 30; died, August 28, in the Woman's Hospital, Philadelphia, of pernicious anemia.

William L. Kneedler ⊕ Major, U. S. Army, retired, Coronado, Calif.; Jefferson Medical College of Philadelphia, 1879; entered the army as assistant surgeon in 1883 and was retired in 1906 for disability in line of duty; veteran of the Spanish-American War; aged 75; died in September.

Murrett Fauquier De Lorme ⊕ Brooklyn; Long Island College Hospital, Brooklyn, 1900; member of the American College of Physicians; formerly clinical professor of medicine at his alma mater; on the staff of the Lutheran Hospital; aged 62; died, September 8, of heart disease.

Guy Herbert Jacobson, Taylorville, Ill.; Chicago College of Medicine and Surgery, 1916; Northwestern University Medical School, Chicago, 1922; member of the Illinois State Medical Society; served during the World War; aged 39; died, September 8, of osteogenic sarcoma.

Walter Haskell Harper, Gadsden, Ala.; Medical College of the State of South Carolina, Charleston, 1916; member of the Medical Association of the State of Alabama; county health officer; aged 37; died, September 6, of a self-inflicted bullet wound.

David A. Ledbetter, Crandall, Texas; Barnes Medical College, St. Louis, 1900; member of the State Medical Association of Texas; aged 54; died, April 14, in the Baylor Hospital, Dallas, of pneumonia, following an operation for cholelithiasis.

Ralph Randolph Holmes ⊕ Chicago; College of Physicians and Surgeons, Chicago, 1906; formerly senior instructor in medicine at his alma mater; on the staff of the Englewood Hospital; aged 56; died, September 26, of chronic myocarditis.

William Jacob Egloff ⊕ Mason City, Iowa; Chicago Medical College, 1887; member of the American College of Surgeons; aged 67; died, September 8, in St. Luke's Hospital, Chicago, of coronary thrombosis and pernicious anemia.

Lewis Ernest Martin ⊕ Anguilla, Miss.; Medical Department of the Tulane University of Louisiana, New Orleans, 1905; past president of the Sharkey County Medical Society; aged 49; died suddenly, September 6, of angina pectoris.

Samuel Porter Tuttle, Grand Rapids, Mich.; University of Michigan Homeopathic Medical School, Ann Arbor, 1898; member of the Michigan State Medical Society; aged 61; died, August 31, in Diamond Lake, of cerebral hemorrhage.

Reed Burns, Dalton, Pa.; University of Michigan Medical School, Ann Arbor, 1876; member of the Medical Society of the State of Pennsylvania; aged 85; died, August 23, in Glenburn, of arteriosclerosis.

August Edward F. Grempler, Baltimore; Baltimore Medical College, 1889; on the staffs of the Franklin Square and West Baltimore General hospitals; aged 64; died, August 8, of chronic myocarditis.

Sumner E. Darling, Hardwick, Vt.; University of Vermont College of Medicine, Burlington, 1882; member of the Vermont State Medical Society; aged 73; died, April 8, of angina pectoris.

Hiram Belden Ormsby ⊕ Cleveland; Cleveland College of Physicians and Surgeons, 1897; aged 59; died, September 23, in a local hospital, of peritonitis, following an operation for appendicitis.

Frank Thomson Brough, New York; Medical Department of Columbia College, New York, 1889; aged 69; died, September 20, in the Nassau Hospital, Mineola, of poison, self-administered.

Jane Crombie Trull, Elgin, Ill.; Bennett College of Eclectic Medicine and Surgery, Chicago, 1905; member of the Illinois State Medical Society; aged 58; died, September 6, of heart disease.

Theodore Fred Estel, Altenburg, Mo.; Marion-Sims-Beaumont Medical College, St. Louis, 1902; member of the Missouri State Medical Association; aged 50; died, August 26, of nephritis.

John Alonzo Rowles ⊕ La Crosse, Wis.; Rush Medical College, Chicago, 1883; on the staff of the Methodist Hospital; aged 76; died, September 13, of carcinoma of the prostate and bladder.

Charles O. Wiltfong ⊕ Chesterton, Ind.; College of Physicians and Surgeons, Chicago, 1901; aged 54; was instantly killed, September 9, in an automobile accident near Belleville, Ont.

George F. Hale, Detroit; Detroit College of Medicine and Surgery, 1917; member of the Michigan Medical Society; served during the World War; aged 51; died, August 31.

Albert Russell Hornbeck ⊕ Lincoln, Neb.; Lincoln Medical College, 1910; aged 46; on the staff of the Lincoln State Hospital, where he died, August 2, of heart disease.

Raymond Jacob Bower ⊕ Williamsport, Pa.; Jefferson Medical College of Philadelphia, 1917; aged 38; was found dead, September 7, of illuminating gas poisoning.

Fortunato Hernandez, Los Angeles; National University Faculty of Medicine, Mexico City, Mexico, 1886; aged 68; died, July 23, of arteriosclerosis and cystic nephritis.

William Thomas Johnston ⊕ Chicago; Chicago Medical School, 1926; aged 44; died, September 22, of chronic myocarditis and terminal pulmonary edema.

Arthur LeRoy Wheeler, Mason City, Iowa; Rush Medical College, Chicago, 1875; formerly city health officer; aged 79; died, September 14, of heart disease.

Samuel Holman Simon, Harrisburg, Pa.; Hahnemann Medical College of Philadelphia, 1880; aged 90; died, August 5, of chronic myocarditis and nephritis.

Fred V. Stucky, Muncie, Ind.; University of Louisville (Ky.) School of Medicine, 1884; aged 68; died, September 8, of chronic myocarditis and nephritis.

Claus F. P. Korssell, Chicago; Rush Medical College, Chicago, 1886; aged 67; died, August 27, of cerebral hemorrhage and arteriosclerosis.

David Henry Taylor, Chicago; Miami Medical College, Cincinnati, 1878; aged 82; died, September 25, of pernicious anemia and chronic myocarditis.

Charles A. Sewell, Washington, D. C.; Howard University School of Medicine, Washington, 1893; aged 62; died, August 31, of chronic nephritis.

Henry Carter, Bringhurst, Ind.; Eclectic Medical Institute, Cincinnati, 1892; aged 81; died suddenly, September 5, of cerebral hemorrhage.

Robert Young Hindman, Columbia, Ky.; University of Louisville School of Medicine, 1902; aged 56; died, August 14, of diabetes mellitus.

Gracchus Crawford Harris ⊕ Courtney, Texas; Medical College of Alabama, Mobile, 1890; aged 54; died, August 19, of angina pectoris.

Frederick Fraley Price, Carbondale, Pa.; Jefferson Medical College of Philadelphia, 1891; aged 67; died suddenly, August 5, of heart disease.

Robert Coyle, Philadelphia; Jefferson Medical College of Philadelphia, 1885; aged 70; died suddenly, September 9, of angina pectoris.

William Blair Clark, New Orleans; Southern Medical College, Atlanta, 1898; aged 50; died, in May, of cerebral hemorrhage.

Henry Bently Webster, Kentville, N. S., Canada; Medical Department of Columbia College, New York, 1872; died, June 5.

Harry L. Sickel ⊕ Woodbury, N. J.; Kentucky School of Medicine, Louisville, 1894; aged 62; died, in April.

Bureau of Investigation

BASY BREAD

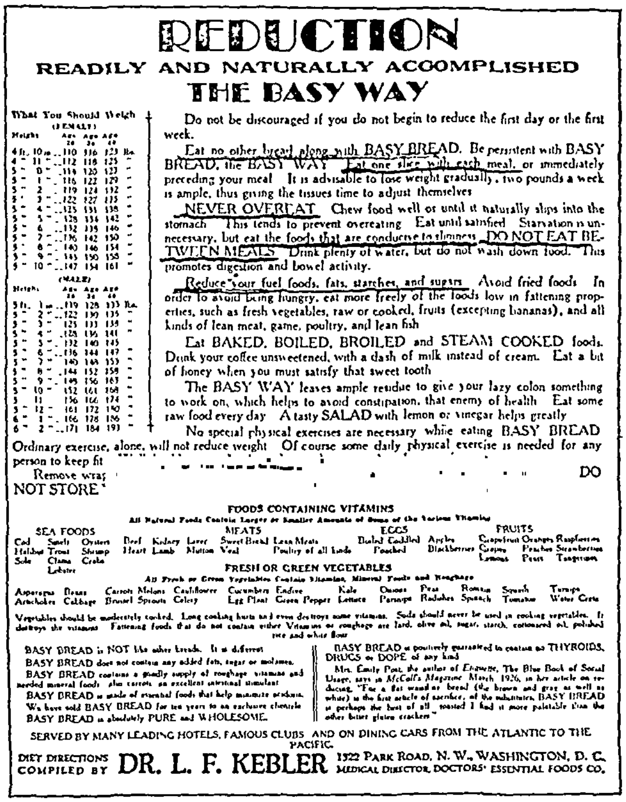
The Use of a Placebo in the Treatment of Obesity

More than twelve years ago, this department of The Journal contained a brief article on Basy Bread, which at that time was being sold under such claims as:

> "Three Slices a Day Will Drive the Fat Away."
>
> "Reduce Easily and Naturally. Eat Basy Bread and Grow Thin."
>
> "Basy Bread, the Health Bread, by its chemical action, destroys the fat already accumulated, and drives it out of the body."
>
> "It is unquestionably the safest, sanest, surest most natural and inexpensive method of reducing fat ever conceived."

At the time of the previous investigation, The Journal published the following analysis of Basy Bread, comparing it with the average graham bread:

	Basy Bread in 1918	Average Graham Bread
Moisture	37.11 per cent	34.80 per cent
Carbohydrates	47.72 per cent	53.40 per cent
Protein	11.98 per cent	8.93 per cent
Fat	1.09 per cent	2.03 per cent
Ash	2.06 per cent	1 59 per cent
Calories	1,166	1,075



REDUCTION

READILY AND NATURALLY ACCOMPLISHED

THE BASY WAY

What You Should Weigh

(FEMALE)

Height	Age 20	Age 30	Age 40	
4 ft. 10 in.	110	116	123	lbs.

6 " 1 "	166	178	186	"
6 " 2 "	171	184	193	"

Do not be discouraged if you do not begin to reduce the first day or the first week.

Eat no other bread along with BASY BREAD. Be persistent with BASY BREAD, the BASY WAY. Eat one slice with each meal, or immediately preceding your meal. It is advisable to lose weight gradually, two pounds a week is ample, thus giving the tissues time to adjust themselves.

NEVER OVEREAT. Chew food well or until it naturally slips into the stomach. This tends to prevent overeating. Eat until satisfied. Starvation is unnecessary, but eat the foods that are conducive to slimness. DO NOT EAT BETWEEN MEALS. Drink plenty of water, but do not wash down food. This promotes digestion and bowel activity.

Reduce your fuel foods, fats, starches, and sugars. Avoid fried foods. In order to avoid being hungry, eat more freely of the foods low in fattening properties, such as fresh vegetables, raw or cooked, fruits (excepting bananas), and all kinds of lean meat, game, poultry, and lean fish.

Eat BAKED, BOILED, BROILED and STEAM COOKED foods. Drink your coffee unsweetened, with a dash of milk instead of cream. Eat a bit of honey when you must satisfy that sweet tooth.

The BASY WAY leaves ample residue to give your lazy colon something to work on, which helps to avoid constipation, that enemy of health. Eat some raw food every day. A tasty SALAD with lemon or vinegar helps greatly.

No special physical exercises are necessary while eating BASY BREAD. Ordinary exercise, alone, will not reduce weight. Of course some daily physical exercise is needed for any person to keep fit

Remove wra [illegible] DO NOT STORE [illegible]

FOODS CONTAINING VITAMINS

All Natural Foods Contain Larger or Smaller Amounts of Some of the Various Vitamins

SEA FOODS
Cod Smelt Oysters
Halibut Trout Shrimp
Sole Clams Crabs
Lobster

MEATS
Beef Kidney Liver Sweet Bread Lean Meats
Heart Lamb Mutton Veal Poultry of all kinds

EGGS
Boiled Coddled
Poached

FRUITS
Apples Grapefruit Oranges Raspberries
Blackberries Grapes Peaches Strawberries
Lemons Pears Tangerines

FRESH OR GREEN VEGETABLES

All Fresh or Green Vegetables Contain Vitamins, Mineral Foods and Roughage

Asparagus Beans Carrots Melons Cauliflower Cucumbers Endive Kale Onions Peas Romaine Squash Turnips
Artichokes Cabbage Brussel Sprouts Celery Egg Plant Green Pepper Lettuce Parsnips Radishes Spinach Tomatoes Water Cress

Vegetables should be moderately cooked. Long cooking hurts and even destroys some vitamins. Soda should never be used in cooking vegetables. It destroys the vitamins. Fattening foods that do not contain either Vitamins or roughage are lard, olive oil, sugar, starch, cottonseed oil, polished rice and white flour.

BASY BREAD is NOT like other breads. It is different.

BASY BREAD does not contain any added fats, sugar or molasses.

BASY BREAD contains a goodly supply of roughage, vitamins and needed mineral foods, also carrots, an excellent intestinal stimulant.

BASY BREAD is made of essential foods that help minimize acidosis.

We have sold BASY BREAD for ten years to an exclusive clientele.

BASY BREAD is absolutely PURE and WHOLESOME.

BASY BREAD is positively guaranteed to contain no THYROIDS, DRUGS or DOPE of any kind.

Mrs. Emily Post, the author of *Etiquette, The Blue Book of Social Usage*, says in *McCall's Magazine* March, 1926, in her article on reducing, "For a fat woman bread (the brown and gray as well as white) is the first article of sacrifice, of the substitutes, BASY BREAD is perhaps the best of all, toasted I find it more palatable than the other bitter gluten crackers."

SERVED BY MANY LEADING HOTELS, FAMOUS CLUBS AND ON DINING CARS FROM THE ATLANTIC TO THE PACIFIC.

DIET DIRECTIONS COMPILED BY DR. L. F. KEBLER 1322 PARK ROAD, N. W., WASHINGTON, D. C. MEDICAL DIRECTOR, DOCTORS' ESSENTIAL FOODS CO.

According to the manufacturers at that time, Basy Bread was made from coarse-ground, hard whole wheat, preserved and sweetened with ground figs and containing vinegar, salt and water.

The late Dr. Harvey W. Wiley in 1918 was connected with *Good Housekeeping* and acted as a censor for the advertising of food products for that magazine. He analyzed Basy Bread and summed up the case against this dietetic nostrum in the following words: "There is one way in which Basy Bread will reduce; that is, don't eat any of it, nor much of any other kind."

It was pointed out in the previous article that the joker in the Basy Bread exploitation lay in the fact that the person who was using Basy Bread was told that she (it was usually she) must greatly diminish the amount of bread, potatoes, oils, fats and sugars in the diet while using the "bread." Quite naturally, the obese could have reduced just as effectively had they followed the dietetic instructions that came with the Basy Bread and thrown the "bread" itself in the garbage can!

But, apparently, Basy Bread still flourishes for the Bureau of Investigation continues to get inquiries regarding it. Because of the continued interest in this preparation the American Institute of Baking was asked during the past year to analyze the Basy Bread then found on the market, so that this information could be passed on to the medical profession and the public. Dr. C. B. Morison, Director of Laboratories of the American Institute of Baking, kindly consented to have this work done, and in due time submitted the following figures:

Moisture	35.24 per cent
Protein (N × 6.25)	11.04 per cent
Nitrogen free extract	47.64 per cent
Crude fiber	1.21 per cent
Fat	2.54 per cent
Ash	2.33 per cent
Calories per pound	1,168.2

Again we see that the energy value of Basy Bread is more than equal to that of average graham bread and is almost equal to that of white bread, which averages 1,200 calories per pound for bread of usual moisture content and composition. *Essentially the same directions come for the use of Basy Bread today* as were sent out twelve years ago. Some of these directions are:

> "Eat no other bread."
>
> "Do not eat between meals."
>
> "Eat one slice with each meal."
>
> "Walk briskly several miles a day."
>
> "Do not partake of heavy cream soups."
>
> "Eat the foods that you know will be inducive to slimness."

According to a letter written by the "Medical Director" of the "Doctors' Essential Foods Company, Inc." that puts out Basy Bread, this product is made of "whole wheat flour, soy bean flour, carrots, fruits and yeast." From the same source we get the admission that "Basy Bread contains about the same number of calories as white bread."

Obviously Dr. Wiley's statement of many years ago is just as applicable to Basy Bread today as it was when it was written. It is patent that any woman who will cut down her bread intake to a single slice three times a day, who will reduce her intake of fats, starches and sugars, who will substitute a "dash of milk instead of cream," who will "walk briskly several miles a day"—will, in all human probability, reduce her weight, even though she never hears of Basy Bread and continues to use the much more palatable ordinary white bread in her diet. For people who are so constituted that they cannot be made to follow a diet without a certain amount of hocus-pocus and the expenditure of money, Basy Bread may serve a useful purpose. For all practical purposes, however, the obese who reduce by the Basy Bread method are being "kidded by experts."

MORE MISBRANDED NOSTRUMS

Abstracts of Notices of Judgment Issued by the Food and Drug Administration of the United States Department of Agriculture

Red Caps.—The Campbell Laboratories, St. Joseph, Mo., shipped in January, 1929, to Kansas a quantity of Red Caps that were declared misbranded. The product consisted of capsules containing antipyrine, asafetida, podophyllin, red pepper, starch and a trace of alkaloids. The claim that it was a remedy for influenza was declared false and fraudulent. The Campbell Laboratories in March, 1929, having appeared as claimants, judgment of condemnation and forfeiture was entered and the court ordered that the product be released to the company on payment of costs and the execution of a bond conditioned in part that the preparation be relabeled.—[*Notice of Judgment 16576; issued February, 1930.*]

Gasidal.—The Gasidal Company, Kansas City, Mo., shipped to Atchison, Kan., in December, 1928, a quantity of Gasidal that was declared misbranded. Analysis showed the product to consist essentially of baking soda, magnesium carbonate, bismuth subnitrate, and starch, flavored with peppermint. The claims to the effect that it was a positive relief for all forms of gastro-intestinal disturbances and specifically useful in duodenal ulcers, gallbladder disease, gastric neurosis, pelvic infections in women, etc., were declared false and fraudulent. In April, 1929, D. J. Sullivan of Kansas City, Mo., appeared as claimant and judgment of condemnation was entered, and the court ordered that the product be released to Sullivan on payment of costs and the execution of a bond conditioned in part that the preparation be relabeled.—[*Notice of Judgment 16587; issued February, 1930.*]

Stout's Cold Tablets.—D. C. Leo and Company of Des Moines, Iowa, shipped into West Virginia in January, 1929, a quantity of Stout's Cold Tablets that were declared misbranded. The chemists found the tablets to contain acetanilide, alkaloids of nux vomica and extracts of plant drugs, including a laxative drug. The claim that it was a remedy for influenza was declared false and fraudulent. In May, 1929, judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed.—[*Notice of Judgment 16594; issued February, 1930.*]

Flu-Caps.—Murray C. Kalis and Company, St. Joseph, Mo., shipped into Iowa in January, 1929, a quantity of Kalis' Laxative Flu-Caps which were declared misbranded. Analysis showed the capsules to contain red pepper, ginger, aloin, acetanilide, asafetida, camphor, epsom salt and a laxative plant drug. The claims that this preparation was a remedy for malaria, chills, influenza and various other conditions, were declared false and fraudulent. In April, 1929, Murray C. Kalis and Company appeared as claimants, and judgment of condemnation and forfeiture was entered and the court ordered that the product be released to the claimant on payment of costs and the execution of a bond conditioned in part that it be relabeled truthfully.—[*Notice of Judgment 16592; issued February, 1930.*]

KALIS'
LAXATIVE
"FLU=CAPS"
REGISTERED U S PATENT OFFICE
FOR COLDS, GRIP AND INFLUENZA
EACH CAPSULE CONTAINS TWO GRAINS ACETANILIDE
Prepared by MURRAY C. KALIS & Co., St. Joseph, Mo.
50¢

Kidder's Cold and Grippe Tablets.—Samuel Kidder and Company of Boston shipped in December, 1928, into New Jersey a quantity of Kidder's Cold and Grippe Tablets that were declared misbranded. The chemists reported that the tablets contained phenacetine, salol, caffeine and citric acid. The product was declared misbranded, first, because the label failed to bear a statement of the presence and quantity of phenacetine present; it was further declared misbranded because the claim that it was a remedy for influenza was declared false and fraudulent. In July, 1929, judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed.—[*Notice of Judgment 16593; issued February, 1930.*]

Klein's Cold and Grippe Capsules.—Brewer and Company, Worcester, Mass., shipped in December, 1928, to New Jersey a quantity of Klein's Cold and Grippe Capsules that were declared misbranded. Analysis showed the capsules to contain acetanilide, cinchona alkaloids, phenolphthalein, aloin, sugar and starch. The claim that it was a remedy for influenza was declared false and fraudulent and in July, 1929, judgment of condemnation and forfeiture was entered and the court ordered that the product be destroyed.—[*Notice of Judgment 16600; issued February, 1930.*]

Correspondence

GYNERGEN

To the Editor:—We have seen the letter of Mr. Walter R. Fletcher of the British Medical Research Council concerning Gynergen (THE JOURNAL, September 6, p. 746).

The statement objected to is found in a booklet issued by us early in 1928. It was based on evidence then in our files in New York which evidence, indeed, remained the only one we had up to the time we saw the letter of the British Research Council: namely, passages in the *Pharmaceutical Journal* of February 20, 1926: "It will be assumed that the therapeutically active substance is the specific alkaloid, ergotamine. . . . As standard, a sample of ergotamine tartrate is available prepared by the Sandoz Chemical Works. . . . After consultation with the Director of the Department of Biological Standards, Medical Research Council, it has been decided to approve as good samples of ergot, those containing not less than 1 mg. per gram of the specific alkaloid." Again, in the *Pharmaceutical Journal* of March 13, 1926, the text of the label of tested products is prescribed to be worded as follows: ". . . Cc. of this preparation contains 1 mg. ergotamine, as determined by a biological test carried out by the Pharmaceutical Society of Great Britain."

Again—and this is most important—in the *Pharmaceutical Journal* of April 9, 1927 (p. 384), Burn and Ellis themselves make the following statement: "By the courtesy of the Sandoz Chemical Works, samples of ergotamine tartrate were placed at our disposal at the beginning of our work and *throughout the main portion of it we have used ergotamine as a standard with which to compare extracts of ergot.* We have also received a sample of ergotoxine phosphate through the kindness of Mr. F. H. Carr, C.B.E., of the British Drug Houses, *and having confirmed its pharmacological identity with ergotamine* we have adopted it as the standard for general use." (Italics ours.)

The reasons why, after the work had been done with ergotamine, the standard was changed from easily soluble and easily kept ergotamine tartrate to ergotoxine phosphate, difficult to purify, less stable, less soluble and which requires special precautions for its conservation, are not pertinent here. The facts remain that ergotamine tartrate *was* adopted as a standard and that an important member of the British Research Council *was* consulted.

The booklet on Gynergen referred to has been out of print for a rather long time. We shall continue to adhere strictly to the rules of the Council on Pharmacy and Chemistry of the American Medical Association as regards the advertising of Gynergen.

SANDOZ CHEMICAL WORKS, INC.,
E. W. MARTI, Manager.

BLOOD TESTS FOR PATERNITY

To the Editor:—Since 1910, when von Dungern and Hirschfeld proved that the inheritance of the group-specific substances proceeded according to Mendel's law, the medicolegal aspects of this phenomenon have been recognized and utilized. *In its* simplest form, they showed that the agglutinogen A or B does not appear in the blood of the infant unless it is present in at least one of the parents. Their contention has since been corroborated by Ottenberg and others in large series of cases.

In a study, "Iso-agglutinins in the New-Born" (*Am. J. Dis. Child.* **36**:54 [July] 1928), I presented the results of an investigation which added to the available evidence that the iso-agglutinins found in the cord blood and in the circulation of the new-born infant are in large part derived from the mother as a consequence probably of placental transmission. The initial iso-agglutinins may disappear but in the course of infancy agglutinogens and agglutinins of the infant's own manufacture make their appearance and the blood groups are definitely established. The complete disappearance or diminution in titer of the transmitted iso-agglutinins within ten days after birth was observed in twenty-seven of forty-one cases.

The significance of this train of events was illustrated in two cases encountered in this study. In the two infants the cord serum showed a and b iso-agglutinins and the cells no receptors. The blood groups were like those of the mother, group 0. Reexamination of the blood of the infants in ten and seven days, respectively, failed to reveal any trace of either iso-agglutinin. At ten weeks in one case the A receptor and b iso-agglutinin were present together, and in the other at three months the B receptor and a iso-agglutinin were in evidence. In other words, at birth and for a short time thereafter the infants' blood belonged to group 0 only to be replaced later by their own groups A and B. These are instances in which the iso-agglutinins that disappeared did not properly belong to the new-born infants but had been acquired by placental transmission from the mother. Since both iso-agglutinins were originally present in the blood of the infants and the receptors A and B were absent, they belonged to group 0 and in courts of law would be so regarded. With the loss of one or both iso-agglutinins and the development of the agglutinogens, the problem of parentage would again be thrown open for discussion. Caution must be exercised not alone in the interpretation of group 0 cases but also those in which both mother and offspring fall in group A or B. It is conceivable in the light of this study that the new-born may lose the b or a iso-agglutinin of these groups and with the later acquisition of the remaining cell receptor fulfil the requirements of group AB.

The conclusion reached in this study and one that I would emphasize again is that it would be wise from the medicolegal standpoint to defer these tests for an arbitrary period of at least two weeks following birth.

Dr. Wiener's suggestion that the blood be examined for the M and N agglutinogens of Landsteiner and Levine is a valuable one, particularly when the inheritance of the factors A and B is inconclusive.

Carl H. Smith, M.D., New York.

and Child's Hospital.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted on request.

POSITIVE WASSERMANN REACTION IN PREGNANCY

To the Editor:—Is one justified in giving antisyphilitic treatment to a woman who was found with a 4+ Wassermann reaction while in hospital for childbirth? She has no history or other signs of syphilis. Three Wassermann reactions have been positive, and a Kahn test by the state laboratory is positive. She has a husband whose blood is normal. She and two children are healthy. A. L. Nickerson, M.D., Kankakee, Ill.

Answer.—There is no unity of opinion concerning the significance of a positive Wassermann reaction during pregnancy. When other signs and symptoms of syphilis are present there is, of course, no room for doubt. However, when a positive Wassermann or Kahn test is found in a pregnant woman who has no history or physical signs of syphilis, a disagreement arises. This is especially true when, as in the case cited, the patient's husband and children are apparently healthy. Some syphilologists and obstetricians believe that a positive blood reaction indicates syphilis regardless of whether or not the patient is pregnant. Other authorities maintain that occasionally in pregnancy a woman without syphilis may have a positive Wassermann reaction. De Lee (Principles and Practise of Obstetrics, ed. 5, p. 529) says that more than thirteen deaths of gravidas from arsphenamine have been recorded and that therefore if a positive Wassermann reaction is the only sign of syphilis, the husband's being negative and there being no clinical history of the disease, arsphenamine may be omitted until after delivery but milder antisyphilitic treatment instituted.

If the patient cited has been delivered, specimens of her blood should be sent to two different laboratories for a repetition of the Wassermann and Kahn tests. It might also be advisable to repeat the test on the husband. If the patient has not yet been delivered, it is preferable to wait until the baby is born before repeating the tests. The Wassermann reaction in the new-born baby during the first few weeks of life is unreliable, but a roentgenogram of the long bones may yield useful information. If repeated tests of the patient's blood are positive, antisyphilitic treatment should be given.

DERMATITIS AFTER NEOARSPHENAMINE

To the Editor:—In a patient with early secondary syphilis, developing an exfoliative dermatitis following the fourth 0.9 Gm. dose of neoarsphenamine with three other graduated doses of neoarsphenamine previously in a period of four weeks' intensive treatment: 1. What regimen would you recommend to combat the syphilitic infection from this point on (six weeks since onset)? The patient has still a moderate exfoliation, that is, six weeks from the onset now. Sodium thiosulphate was used successfully to combat the acute toxicity. 2. Would you advise mercury or bismuth when exfoliation subsides? 3. If not, how soon could active antisyphilitic treatment be instituted? Would it be advisable to start on 0.3 Gm. of neoarsphenamine, graduating to 0.6 Gm. as the highest dose, instead of 0.9 Gm. as the highest dose at weekly intervals when arsenic therapy is again started? 4. Would you advise the use of small doses of potassium iodide during the present convalescent stage? Please omit name. M.D., Chicago.

Answer.—1 and 2. Bismuth therapy would be preferable. After two or three weeks, in addition to administration of bismuth compounds, neoarsphenamine should be given in doses of 0.3 Gm., which may be increased to 0.45 Gm. later on. Should signs of exfoliative dermatitis occur again after any applications of neoarsphenamine, it should be discontinued indefinitely, and courses of a bismuth salt be given alternately with those of mercury.

3 and 4. Yes.

USE OF INTRASPINAL MEDICATIONS

To the Editor:—Why are injections of serum in the spinal fluid considered by many of advantage over the intravenous method? How does the absorption of a liquid occur when injected in the cerebrospinal fluid? In the last epidemic of infantile paralysis the intravenous treatment appeared to have given better results than the treatment made by injecting the convalescent serum into the spinal liquid. Why? Please omit name.

M.D., St. Paul.

Answer.—It is because elimination into the cerebrospinal fluid is slow that, in cerebrospinal meningitis, subarachnoid injection is required and eminently successful, because the serum is antibacterial in action and must come into intimate contact with the organisms to display efficiency. Absorption occurs from the cerebrospinal canal with remarkable rapidity; and, according to one theory, chiefly by the choroid plexus. If the theory is correct—and it probably is—that the poliomyelitis virus is primarily distributed through the blood, the greater efficiency of the intravenous injection of the antibodies is readily comprehended; and, if administered before the stage of meningeal invasion, intraspinal injection would not be required or desirable, because, for some unknown reasons, the latter nearly always produces a considerable aggravation of symptoms. In the stage of established meningeal involvement, the sparing intraspinal administration of 10 or at most 15 cc. of serum given at once and not repeated, together with the liberal (100 cc.) and repeated (every ten to twelve hours) intravenous administration of convalescent serum will probably give the best results.

THERAPEUTICS OF IODATE

To the Editor:—Can you furnish me with any information regarding iodate in the treatment of chronic arthritis? Kindly include physiologic effects, clinical indications, and where it may be obtained.

L. R. Belmont, M.D., Camillus, N. Y.

Answer.—Iodate is changed in the presence of reducing substances to iodide and possibly also to some organic iodine compounds. The systemic action of iodate is similar to that of iodine and iodides. In toxic doses, iodate produces gastro-enteritis, collapse and coma. As iodate is hemolytic; it is toxic on intravenous injection; it has not found a place in medicine. Sodium iodate and potassium iodate are prepared by a number of manufacturers of chemicals, such as Mallinckrodt, Merck and J. T. Baker, and marketed by all dealers in chemical reagents.

ENLARGEMENT OF BURSA AT ANKLE

To the Editor:—I have a patient who has considerable enlargement of the bursae of the ankles. The condition is apparently the result of frequent sprains and the wearing of improperly fitted shoes, especially those too short. The bursae have enlarged to such an extent that they feel like bags of water under the skin and cause considerable deformity. Will you please outline form of treatment which will correct the condi? tion? Kindly omit name. M.D., West Virginia.

Answer.—If this patient has been examined carefully for foci of infection and they have either been undiscovered or removed and the condition of enlargement of the bursae persists, the treatment resolves itself into nonoperative and operative. The nonoperative consists of the continuous wearing of a compression bandage during weight bearing, or aspiration and injection of a mixture of camphor and phenol. The operation consists of complete removal of the synovial sac.

ABSORPTION OF PHENOL

To the Editor:—I would like to have information from your department relative to phenol absorption. My former preceptor, Dr. M. P. Ravenel, taught me that an injection of a drachm of phenol was less liable to poison than a drachm of phenol in several ounces of water, claiming that weak solutions of phenol absorbed while strong solutions caused an escharotic membrane through which absorption took place very slowly. Several books published on the treatment of hemorrhoids by the injection of phenol give varying strengths for injections. The strengths run from 5 to 20 per cent in solutions of water, glycerin or oil. In all these mentioned, however, the dosage recommended is from 5 to 10 drops. A recent publication, published by F. A. Davis Company, 1930, written by Lawrence Goldbacher, on page 135 lists 19 and 20 cc. in one injection of *a 5 per cent phenol solution in oil. In the treatment for pruritus ani* the same author in the same publication injects 10 cc. of the same strength phenol solution one-half inch external to the anus through the most intense point of itching at a depth of three-fourths inch. I should like to know your opinion regarding toxicity and the effect of this solution on live muscle tissue. Please omit name. M.D., Wisconsin.

Answer.—There is no doubt some truth in Dr. Ravenel's assertion, especially if the statement is changed to read that in caustic strength it is absorbed more slowly rather than very slowly, for one of the characteristic features of phenol poisoning, no matter how it is administered, is the rapid onset of unconsciousness. The dosage employed for injections for hemorrhoids and pruritus ani is safe, as a fatal quantity would probably not be reached until a dose of 8 Gm. of phenol is exceeded. The effect of these injections is sclerosing rather than caustic. Indeed, the increasing popularity and safety of this procedure lies in the fact that quick destruction by caustic action has been abandoned in favor of slow destruction by exciting connective tissue overgrowth.

DOUBLE-DISK AND VALVE-TUBE RECTIFICATION IN X-RAY APPARATUS

To the Editor:—Kindly state the essential difference between double-disk and valve-tube rectification in x-ray apparatus and the prevalence of the use of each at present and the apparent trend. Omit name. M.D., Ohio.

Answer.—The essential difference between disk, either double or single, and valve-tube rectification in x-ray apparatus is that one is mechanical, the disks being rotated by a synchronous motor, and the other is electronic, the rectification being accomplished by one or more vacuum tubes which permit the flow of current in only one direction. The mechanical rectification, at high voltage, permits no current to pass through the tube during certain periods of rectification. With the valve-tube type there is always some current passing which may be at approximately the voltage at the terminals of the high voltage transformer or some fraction of this quantity. In no commercial machine is the current continuous at the maximum voltage output. The trend of construction in Europe is toward the valve-tube rectification apparatus. In this country one firm is pushing it strongly. Most other manufacturers are adhering to the disk type of rectification. It is generally acknowledged that the engineering problems connected with the valve-tube apparatus have not yet been completely solved. The advantage lies chiefly in the fact that the machines are silent. The valve-tube type generates slightly more x-rays than the mechanical at the same voltage and amperes.

The practical answer to the subscriber's problem is that the institution should purchase a type of machine which offers the best conditions for repair service. Any x-ray machine at the present time will deliver vastly more current than an x-ray tube will stand, and it makes little difference what the wave form is. The essential is quick repair in case of a breakdown. Therefore the form that offers the best and longest guarantee is the one that should be purchased.

PREGNANCY AT VARIOUS AGES

To the Editor:—What information or statistics have you on the occurrence of pregnancy in girls getting married at the age of 35, compared to those getting married younger, say at 25. Is it a fact that maiden ladies go through the menopause at an earlier age than married women? If so, what is the approximate age? Kindly omit name. M.D., Milwaukee.

Answer.—The age of greatest fertility in women is between 20 and 30 years, and of this period the most favorable years are between 20 and 24. Duncan's studies on this subject (Fecundity, Fertility and Sterility, 1871) led him to conclude that "about 7 per cent of all marriages are without offspring; that those married at ages from 20 to 24 inclusive are the most fertile; and that after that age, sterility gradually increases according to the greater age at the time of marriage." Nearly all authorities agree with Duncan's statement. Hence early marriages are highly desirable from the standpoint of fertility.

According to Sanes (Statistical Study of Age of Menopause, Tr. Sect. Obst., Gynec. & Abd. Surg., A. M. A., 1918) the menopause occurs earlier in unmarried women than in those who have had an active sexual life, especially those who have given birth to a number of children. The approximate age is difficult to state because the climacterium depends on many factors. The most important factors other than maternity are climate, race, heredity, illness, social conditions, obesity and age of puberty. Contrary to the view generally held by the public, the earlier the menstrual function begins, the longer it continues. In temperate climates about 50 per cent of all women have their menopause between 45 and 50 years of age, 25 per cent between 40 and 45 years, 12.5 per cent between 35 and 40 years, and the remainder between 50 and 55 years.

TREATMENT OF TUBERCULOUS GLANDS

To the Editor:—Would you kindly inform me as to the consensus of opinion of the medical profession for the proper treatment of tuberculous glands. Is it extirpation or should dependence be placed on such measures as tuberculin, quartz light therapy, sunlight, rest and general hygiene? Please omit name. M.D., China.

Answer.—Enlarged glands are usually the result of infection elsewhere; therefore, the focus should be sought and eliminated if possible. When the glands have already broken down, the obvious treatment is incision. As so many swollen glands are due to tuberculosis, it is advisable to examine the patient carefully to determine the presence or absence of this disease. According to Neumann, in a recent publication, supraclavicular glands, diminishing in size from above downward, indicate a lymphatic infection arising in the mouth or pharynx. On the contrary, glands diminishing in size from below upward indicate a lymphogenous propagation from an apical tuberculous pleurisy; it will be seen that, in case of such infection, extirpation of a few cervical glands cannot be of much avail when the chain extends down into the chest. In some cases of tuberculous glands good results have been obtained from the application of a Pirquet vaccination above (to) the glands, in the region drained by the glands. Otherwise tuberculin has not been of much good. General hygienic measures are, of course, to be recommended.

PARONYCHIA

To the Editor:—I have developed a peculiar condition of the finger nails (three on one hand and two on the other) which I am unable to diagnose. A perfectly dry area apparently of the epidermis appears at the side or the base of nail and in a few days scales off. The denuded area becomes tender to touch; there is no pain, itching or moisture. The nail does not seem to be involved. What is it and what shall I do for it? After the first or original scale there is a fine thin scaling. The condition would seem due to a fungus. F. E. R. Burgess, M.D., Bethany, Mo.

Answer.—The paronychia here described could be traumatic, mycotic or due to some other parasitic agent. A 3 per cent salicylic acid ointment probably would effect its removal.

USE OF GOLD SODIUM THIOSULPHATE

To the Editor:—I should like to make inquiry as to the efficiency of gold sodium thiosulphate in clearing up brown spots on the skin, produced evidently by loss of pigmentation in one portion and accumulation in other portions of the skin. It has been brought to my attention that hypodermic injections of this preparation have brought about wonderful results in many patients. William C. Davis, M.D., Columbus, Ohio.

Answer.—The most that can be said about this method of treatment is that it is in the experimental stage, that it is not uniformly successful, and that it is as yet impossible to state definitely in which cases it will succeed and in which it will not. Lindsay (Treatment of Leucoderma with Gold Sodium Thiosulphate, *Arch. Dermat. & Syph.* **20**:22 [July] 1929) believes that it counteracts excessive photosensitivity. The substance is injected intravenously in initial dose of from 30 to 60 mg., increased to 100 mg. The injections are generally given at intervals of one week.

CALCIUM CHLORIDE AND DERMATITIS

To the Editor:—Can you give me any information on calcium chloride as a causative agent of dermatitis? The coal company here is using a solution of calcium chloride to spray coal to keep down dust. Recently a number of the workers have developed a skin rash where the spray came in contact with the skin and where it had gone through the clothing. Please omit name.

M.D., West Virginia.

Answer.—The grade of calcium chloride used for mine or road dusting is far from pure. Even "Merck's" reagent type of calcium chloride accepts as probable impurities traces of such substances as free alkali, alkali salts, nitrates, sulphates and arsenic.

Crude calcium chloride contains much more extraneous materials of the same types, and, in addition, ammonium compounds. Calcium chloride is largely derived as a by-product in the manufacture of soda by the Solvay ammonia process.

Calcium chloride itself has about the same order of toxicity as table salt. Any dermatitis resulting from it is probably attributable to its impurities, of which alkalis or alkali salts are the most likely. Calcium chloride itself, however, in the presence of moisture, yields an acid reaction.

RINGWORM OF NAILS

To the Editor:—Please advise as to cause and treatment of thickening and dying condition of finger and toe nails. A woman, aged 28, who has come under my care for treatment, has been given the antisyphilitic serums and never showed a positive Wassermann reaction. She has a small thyroid enlargement and has had fainting spells. The temperature is normal; pulse, 104; reflexes, normal. I have looked up authors, but could not find this described.

M.D., Oklahoma.

Answer.—This condition may be nutritional or infectious. Ringworm of the nails produces a condition that suggests a dying nail. A scraping properly made will reveal the presence or absence of fungi. If no fungi are found, nutritional disturbances must be considered and in all probability arsenic would be of service here. This would have to be watched carefully and be supervised by a physician. If the trouble is mycotic in nature, the treatment would have to be directed for that disorder.

POSSIBLE MYCOTIC DERMATITIS

To the Editor:—I saw today a man in middle age, a banker, in a good state of health, who presented on his hands and forearms some half dozen groups of round, pin-head size, black spots on or in the skin, which looked precisely as would fine drops of strong silver nitrate after being exposed to light. There was absence of local reaction and subjective symptoms, and the spots would not scrape off. He informs me that his wife and son are similarly affected on the arms, neck and face. The number of spots in a group varies from one to fifteen and the multiple groups have the spots closely aggregated. All three persons have been swimming in the same pool during the recent weeks. The duration of the condition in each case is about a week. Can you suggest the etiology? Please omit name.

M.D., Iowa.

Answer.—Much depends on whether these lesions are in or on the skin. If it means that there are scaly spots, it might be a fungous infection. This could be determined by microscopic examination. If the black spots consist of pigment within the skin, then an entirely different condition would have to be considered. In view of the fact that other people have the same disorder, it is most likely that it is a mycotic dermatitis.

EFFECTS OF X-RAYS ON HEART AND BLOOD

To the Editor:—Kindly advise whether or not x-ray work as a technician has any detrimental effect on the heart? I am perplexed at the present time because of the literature.

J. S. Collins, M.D., Wabasha, Minn.

Answer.—An x-ray technician in normal health and therefore with a normal heart has nothing to fear in the way of any cardiac harm from x-rays in the discharge of his duties when performed under modern approved technical procedure. This refers to protective measures that must always be taken in the presence of x-rays, known to all well informed x-ray operators.

Certain individuals have been found to show blood changes which seem to have been the result of x-ray absorption. A careful worker will have his blood examined periodically and if changes are disclosed thereby will advisedly change his occupation to one less hazardous to him.

Oklahoma June Examination

Dr. J. M. Byrum, secretary of the Board of Medical Examiners of Oklahoma, reports the written examination held at Oklahoma City, June 10 and 11, 1930. The examination covered 12 subjects and included 120 questions. An average of 75 per cent was required to pass. Fifty candidates were examined and passed. The following colleges were represented:

College PASSED	Year Grad.	Per Cent
University of Arkansas School of Medicine	(1930)	84, 89
Northwestern University Medical	(1928)	88
State University of Iowa College c ''		88
University of Oklahoma School of ''		, 78, 80, 81, 81 82 83, 83 83, 84, 84, 84, 8 , , 85, 85, 85, 85, 85, 85, 85, 85, 85, 86, 86, 86, 86, 86, 86, 86, 87, 87, 87, 87, 87, 87, 87, 87, 88, 89, 90, 90

Dr. Byrum also reports 13 candidates licensed through reciprocity with other states, 1 by endorsement of National Board of Medical Examiners credentials; 2 reregistration certificates were issued, according to the act of 1908. The following colleges were represented:

College LICENSED BY RECIPROCITY	Year Grad.	Reciprocity with
Northwestern University Medical School	(1929)	Louisiana
Rush Medical College	(1929)	Illinois
University of Illinois College of Medicine	(1927)	New York
State University of Iowa College of Medicine	(1927)	Iowa
University of Louisville School of Medicine	(1913)	Mississippi

Central Medical College of St. Joseph	(1903)	Reregis.

Iowa Reciprocity Report

Mr. H. W. Grefe, director of examination and licensure of Iowa, reports 16 physicians licensed through reciprocity with other states from Jan. 1, to July 14, 1930. The following colleges were represented:

College LICENSED BY RECIPROCITY	Year Grad.	Reciprocity with
George Washington University Medical School	(1924)	Ohio
Bennett Medical College	(1914)	Illinois
Northwestern University Medical School	(1929, 2)	Illinois
Rush Medical College	(1928) Texas, (1914)	Illinois
Indiana University School of Medicine	*(1925)*	Indiana

University of Louisville School of Medicine	(1928)	Kentucky
Tulane University of Louisiana School of Medicine	(1923)	Louisiana
Barnes Medical College	(1910)	Missouri
St. Louis University School of Medicine	(1929)	Missouri
Creighton University School of Medicine	(1928)	Ohio
University of Nebraska College of Medicine	(1920) (1925)	Nebraska
Jefferson Medical College	(1900)	Colorado
University of Tennessee College of Medicine	(1916)	Tennessee

Book Notices

SYMPOSIUM ON PHYSICAL EDUCATION AND HEALTH. Compiled and edited by Jay B. Nash, Professor of Physical Education and Health, New York University. Assisted by Emma R. Frazier and Marguerite Vollmer. Boards. Pp. 320, with illustrations. New York: New York University Press Book Store, 1930.

At the dedication of the new twelve story building of the school of education at New York University, in February, a three day conference was held on the problems of physical education and health. Twenty-eight of the addresses have been published in book form. The compiling and editing was done by J. B. Nash. This entire symposium emphasizes the part played by physical education in connection with the intellectual power which the individual develops. Its greatest contribution is in the building of skills which will express themselves as wants in leisure time activities. The central theme of the symposium, the oneness of mind and body, given by Dr. L. Vosburgh Lyons, lecturer on neuro-anatomy at New York University, recognizes the opposite categories of the mental and physical. The program at the school of education, coordinating as it does the sciences contributing to health, will fulfil the objectives outlined by the American Physical Education Association which are given in the book. Such a curriculum is needed. Physical education is now required by law in schools of thirty-six states, affecting 95 per cent of the pupils of the country. There is a want of effective organized health programs. One speaker at the conference laid the causes of this to poor coordination in instruction, the lack of comprehension by teachers of what constitutes the health program and, when given, the instruction not being presented in a manner vital to pupils. The symposium on physical education and health is valuable to students as a basis for analyzing the component parts of the profession in the light of its objectives. On page 155 is given a picture of optimal health, and on page 147 the three factors influencing it. Teachers can well follow the plan given to correlate physical education with other activities in their contributions to education. The book represents the latest attitude of education toward the relatively new profession of physical education and can be used as a practical guide.

THE ANTISCURVY VITAMIN IN APPLES. By Mary F. Bracewell, E. Hoyle and S. S. Zilva. Medical Research Council, Special Report Series, No. 146. Paper. Price, 9d net. Pp. 45, with 33 illustrations. London: His Majesty's Stationery Office, 1930.

This report describes an investigation of vitamin C in various varieties of apples and the effects of maturity, soil, age of tree, storage and temperature on the vitamin content. The results are reported of experiments for the detection of any possible correlation between the antiscorbutic potency and the physiologic condition of the plant, maturity of the fruit, soil, age, storage and effect of heat. The experiments are based on the assumption that the vitamin C content of fruit is determined by a number of physiologic factors the revealing of which may disclose information on the nature and identity of the vitamin. Previous investigations have shown that the apple is a poor source of vitamin C. The process of canning or desiccation largely inactivates the vitamin. Apples gradually lose their potency during storage. Apples immersed in 2 per cent salt solution for eighteen hours before processing, however, retain their natural potency. The generally accepted biologic procedure was used for determining the vitamin C potency. The flesh of the apple only and not the peel or core was fed to guinea-pigs. The independent factors—duration of test period, cause of death, first appearance of scorbutic symptoms, degree of scurvy at necropsy and growth — were considered. Six varieties of English apples tested showed considerable differences in antiscorbutic activity. One variety, Bramley Seedlings, was decidedly the most potent. This was true for samples from different localities and picked at different seasons. No direct relationship between potency, age of tree or type of soil was noted. Normally ripe apples and those picked fourteen days before normal ripeness were of like potency. Apples aged in cold storage, 1 C. in air, retain their vitamin C potency better than apples aged at 10 C. in an atmosphere of 10 per cent carbon dioxide, 11 per cent oxygen and 79 per cent nitrogen. Eleven varieties of imported apples showed Canadian apples to be almost as potent as the English dessert variety, and the Australian and New Zealand varieties somewhat less potent. Comparatively slight differences in activity were noted in apples from various places in the same country and maturing at two different seasons of the year. Bramley Seedlings heated in the skin before storage, after cold storage or after gas storage showed little destruction of the vitamin during the heating period. The apples were placed in a drying oven at 160 C. The temperature fell to 115 C., where it was maintained for fifty minutes. The temperature of the core rose to 25 C. after five minutes and to 95 C. at the end of the heating. The experiments did not reveal any functional relationship between the antiscorbutic principle and any other factor studied. The high vitamin C content of Bramley Seedlings attracts special attention. The experiments exclude such factors as age of tree, soil, and season as directly responsible. Other varieties grown under similar conditions were less potent. Whether this property is "racial" or whether it is associated with any other characteristics is yet to be established. It is of interest to the dietitian that Bramley Seedlings have high antiscorbutic potency whether freshly picked or stored and that it persists after heating.

IODIZED OILS AS AN AID TO THE DIAGNOSIS OF LESIONS OF THE SPINAL CORD AND A CONTRIBUTION TO THE KNOWLEDGE OF ADHESIVE CIRCUMSCRIBED MENINGITIS. By Martin Odin and Gösta Runström, in co-operation with Adolf Lindblom. Acta Radiologica, Supplementum VII. Paper. Price, Swed. cr. 15. Pp. 86, with 38 illustrations. Stockholm: P. A. Norstedt & Söner, 1929.

This is an interesting and valuable study of iodized oils used by neurologists. The authors first discuss the anatomy of the subarachnoid space in brief and show that it is divided into an anterior and a posterior compartment, so that in clinically tilting a patient to observe block or partial arrest of iodized oil one must do it with the patient both on his back and on his abdomen. They have experimented with various types of iodized oils in varying amounts and found that some of the oils are rather irritating, especially when given in large amounts. They have found not only that the usual oils are irritating but also that the technic of preparation is such that considerable acetic acid and chloroform is often still present in the oil, which causes marked irritation of the leptomeninx. They have devised a new method of preparation of the emulsion for which they used oil of sesame. This is clinically nonirritating to the meninges. Many cases are reported in detail and their roentgenographic results pictured in several good plates. It is interesting that they have seen several cases with sciatic symptoms which they suspected of being a lumbar arachnoiditis. They confirmed this with iodized oil and at operation were able to relieve the symptoms.

THE ART OF RAPID READING: A BOOK FOR PEOPLE WHO WANT TO READ FASTER AND MORE ACCURATELY. By Walter B. Pitkin, Professor in Journalism, Columbia University. Cloth. Price, $2.50. Pp. 233. New York: McGraw-Hill Book Company, Inc., 1929.

This is one of those books of the class of Arnold Bennett's "How to Live on Twenty-Four Hours a Day," a book that contains much advice that ought to be obvious but that most persons rarely have in concrete form in their minds. And there is a lot of wisdom in it. The author gives many good suggestions on reading and puts them in form that is striking. He is a professor of journalism and the book has a journalese flavor to it. Any one can get some good points on effective reading from the reading of this book, just as any one can get good points from many similar books on other subjects—about how to improve one's grammar, or his handwriting, or his memory, or his conversation, or his elocution, or his bridge. There is much banality in all of them but there is a lot of useful information. The author's main thesis is the point that ought to be perfectly obvious but that most people apparently neglect to realize; namely, the importance of selecting one's reading with care and of picking out the important part of that which one reads. In order to illustrate the subject, he devotes considerable space to the art of skimming in reading. That is a useful art if used judiciously but is one which the average reader is apt so to use as to make his reading superficial and fruitless. And somehow one gets up from the consideration of the art of how to skim in reading with a feeling that for most readers it would be more useful to emphasize the importance of selecting reading with care and then, except the reading which is purely for entertainment, reading carefully —quite the opposite of skimming. But one can spend an interesting evening or two skimming judiciously through this book.

Les thérapeutiques nouvelles: Exposé critique et synthétique applications. Par Gaston Lyon. Paper. Price, 26 francs. Pp. 389. Paris: Masson & Cie, 1930.

The author's aim is to present the newer therapeutics in a "critical and synthetic" manner. He admits that it would be presumptuous to attempt to "stabilize" a science which, like all other sciences undergoing the viscissitudes of progress, may make the truth of today the error of tomorrow. He nevertheless attempts to help the medical practitioner in the selection of suitable remedies for his practice. He endeavors to cover the progress not only in the medicinal but also in the nonmedicinal remedies, including psychotherapy and surgery, to discuss general technic of medication, and to review in chapters on various functional systems the application of these newer remedies to the various important diseases, all within the confines of 380 pages. The result, of course, is sketchy, rather superficial, nevertheless remarkable in its display of familiarity with the newer therapeutic procedures in so vast a domain. All must choose between being profound and narrow or broad and shallow. The author has chosen the latter method as best suited for his *purpose.*

A Textbook for Midwives. By John S. Fairbairn, M.A., B.M., B.Ch., Consulting Obstetric Physician, St. Thomas's Hospital and General Lying-In Hospital, York Road, S.E. Fifth edition. Cloth. Price, $8. Pp. 269, with 119 illustrations. New York: Oxford University Press, 1930.

This is a closely printed, copiously and well illustrated book on obstetrics, intended for English-speaking midwives but one that meets no need in this country. It is about half way between textbooks for nurses and the students' manual. Twenty-nine pages are devoted to the general subjects of anatomy, physiology and bacteriology which might have been left to appropriate textbooks, and thirty-eight are given to the reproductive organs. The description of the mechanism of labor, complicated still further by its presentation as occurring in the side position, is hardly understandable by one not fortified with a knowledge of physics and anatomy. The treatment of all the complications of obstetric practice as presented in the volume is sensible, and agreeable to the latest advances in the art; but one must regret that conditions still exist in which unlearned and unpracticed women are placed in situations where they have to attempt such dangerous operations. It casts a reflection on our civilization. Excellent chapters are given on surgical cleanliness, breech presentation, other pathologic labors, puerperal infection, the care and feeding of infants, venereal disease, and maternal and infant mortality in Britain, making a volume of useful information. If the British midwife knows all there is in this book and has the ability to practice its teachings (both of which postulates may meet a reasonable doubt), she ought to be a safe person in the confinement chamber.

La fisio-patologia del sonno. Per Prof. Dott. Alberto Salmon, docente in neuropatologia nella R. Università di Firenze. Paper. Price, 30 lire. Pp. 211, with illustrations. Bologna: Licinio Cappelli, 1930.

This is a restatement of Professor Salmon's thesis on the cause of sleep, published in French in 1910. The author's clinical observations during the intervening twenty years have only strengthened his conviction that sleep and wakefulness are regulated by the secretory activity of the hypophysis. The nutritive state of the nerve cells concerned in sleep depends on the antitoxic action of the secretion of the anterior lobe and is affected by the vasoconstrictor properties of secretion of the posterior lobe. A large portion of the book is devoted to a discussion of the disorders of sleep (hypersomnia, narcolepsy, dissomnia, hyposomnia, insomnia) and their treatment. Thus, twenty-two groups of pathologic conditions leading to hypersomnia are taken up in some detail. The book should prove of considerable value to the student of sleep and its disorders.

Les érythrémies de l'altitude: Leurs rapports avec la maladie de Vaquez. Etude physiologique et pathologique. Par le Dr. Carlos Monge, professeur de pathologie interne à l'Université de Lima. Préface du Professeur G. H. Roger, Doyen de la Faculté de médecine de Paris. Paper. Price, 22 francs. Pp. 134, with illustrations. Paris: Masson & Cie, 1929.

This work considers not only the erythremia of altitude but also the other physiologic responses. It discusses changes in basal metabolism, the shift in the acid-base equilibrium and the altered constituents of the urine. Studies of the oxygen saturation of the blood, of the elimination of the carbon dioxide and of the change in the carbon dioxide tension are included. The studies were made at various altitudes between 150 and 4,500 meters. While nothing particularly new is offered in this field, the subject has been thoroughly investigated and the results are set forth in detail. The various theories of acclimatization are discussed as well as the relationship between the erythremia of altitude and that of other causes. A fairly comprehensive bibliography is attached. A little more care might have been used in the proof reading, particularly in reference to proper names. It rather annoys the American reviewer to see Osler spelled Oster and Warthin spelled Warting.

An Introduction to Vertebrate Embryology. By H. L. Wieman, Professor of Zoology, University of Cincinnati. Cloth. Price, $4. Pp. 411, with 200 illustrations. New York: McGraw-Hill Book Company, Inc., 1930.

This is an authoritative textbook based on the author's presentation of the subject to premedical students. It has a number of new features; especially commendable are the treatment of cytology in general and the place of the germ cells in it, the discussions of experimental work with its biologic as well as its embryologic implications, and the admirable chapter on placentation. Emphasis is placed on the phases of the subject with which the student can come into personal touch in the laboratory, and the bulk of it accordingly deals with the chick and the pig embryo. The illustrations are for the most part new; they are clear and simple but true to the originals, with few diagrams. The incorrect stock textbook figures of human embryos have been supplanted; but a few more might have been added to convince the medical student, whose prejudices are worth considering nowadays, that he could see no more in human embryos than in the available comparative material of the early stages which he studies. The chapter on the brain reveals the need, as every similar treatment does, of a detailed, comprehensive and objective account of the development of some vertebrate brain, by a competent neurologist, which might serve as a guide for elementary presentations. Probably another Wilhelm His will have to arise before such an account is written.

History of the Orleans Parish Medical Society, 1878-1928. By A. E. Fossier, A.B., A.M., M.D. Cloth. Pp. 238, with illustrations. New Orleans: Albert E. Fossier, 1930.

Professional ethics seems to have been the bone of contention in the early attempts at organizing the Orleans Parish Medical Society. In 1873, reformers organized the Orleans Medical and Surgical Association, and a considerable number of members also belonged to the Orleans Parish Medical Society. The renaissance of scientific activities then centered the interest of physicians and to these men this history is dedicated: "To the Young Men of the Eighties, whose judgment, vision, devotion and acumen fused into a solid body the decadent medical Societies of this City." The history covers the period between 1878 and 1928. The Shreveport Medical Society is credited with the assembling of representatives from different parishes to organize the state society in conformity with the plans of the American Medical Association. In 1890 the new society absorbed the Orleans Medical and Surgical Association.

The History of the Orleans Parish Medical Society, compiled by Dr. A. E. Fossier, puts into permanent form the transactions, which are a replete repository of the astounding advances attending the rapid stride of recent hygienic progress. It is largely based on the journal of Dr. Charles Chassaignac, which is an historical sketch of the society from its beginning to the year 1902. Chassaignac is the oldest living ex-president.

New Orleans is said to have been the scientific laboratory in which was tested and performed the efficiency of some of the noteworthy discoveries in the annals of preventive medicine. Two chapters are devoted to public interest meetings at which symposiums were held to advance or support important hygienic measures in combating epidemics and pestilence. The present generation of physicians will here find how organized medicine in the past handled such momentous questions as hospital abuses of medical charity, chiropractor bills and political control of medical legislation. It forms a convenient book of records of physicians during the fifty year period in which medical science underwent so many revolutionary achievements. An interesting feature is the series of page groups of portraits of members and views of meeting places. The author discounts the verity of the laconic thought that "contemporaries appreciate the man rather than the merit, but posterity will regard the merit rather than the man." In the chapter on honoring distinguished members, full accounts are given of the ceremonies attending the honoring of Drs. C. C. Bass, Ernest S. Lewis and Rudolph Matas. The chronicle on minutes and transactions of the society occupies seventy pages of the book; a roster of members from 1878 to 1928, fourteen pages, and there is a complete index to portraits for ready reference. This public history is a realization of the dream which the author had to redeem from actual oblivion the recorded labors of distinguished predecessors.

Les hypotensions aiguës et subaiguës. Par M. A. Dumas, médecin des hôpitaux. Paper. Price, 30 francs. Pp. 162. Paris: Masson & Cie, 1929.

This small monograph consists largely of discussion and description of the clinical conditions associated with sudden or less abrupt lowering of blood pressure. Animal experimentation has not been developed in this field, if one judges by this work. No electrocardiographic tracings have been used. A few charts of daily blood pressure readings during infection are shown. The symptoms of syncope derived from the brain, eye, ear, blood and other viscera are discussed. Those arising from the heart and the associated observations are described. Various syndromes with acute hypotension as the central etiologic factors are pictured. Hypotension occurring in the course of other diseases is then discussed at length. One is impressed with the thoroughness of clinical study and the plausibility of theoretical argument, while the lack of exact physiologic measurement of the factors concerned is evident.

Mental Aspects of Stammering. By C. S. Bluemel, M.A., M.D., L.R.C.P., Clinical Instructor in Neurology of the University of Colorado School of Medicine. Cloth. Price, $2.50. Pp. 152, with 20 illustrations. Baltimore: Williams & Wilkins Company, 1930.

This work is intended for a simple introduction to practical teachers as well as for patients who stammer. It is in no sense intended as a scientific treatise on stammering. For the purpose, it seems adequate. It may well be used in special classes for this type of patient.

Sensation and the Sensory Pathway. By John S. B. Stopford, M.D., F.R.S., Professor of Anatomy, the University of Manchester. Cloth. Price, $3. Pp. 148, with 19 illustrations. New York: Longmans, Green & Company, 1930.

The author is a distinguished English anatomist who has been working on sensation for the last decade or more. This little book adequately summarizes and discusses the problem of peripheral sensations so that those who would have a general picture of the problems will find it easier to get it here rather than from Head's two large volumes. The author agrees essentially with Head's conception except that he believes deep sensation is also divisible into the epicritic and protopathic types and is conveyed in part at least by the cutaneous nerves. After a description of the facts involved in peripheral sensory losses and the various types of central sensory defects, the author attempts to explain these facts in an argumentative fashion and to combat all those who do not believe in the two types of sensation. New evidence is not added in favor of Head's conceptions. Much is made of the so-called normal protopathic sensation of the glans penis and of the intermediate zone of protopathic sensations after division of a peripheral nerve. The reason for the unequal regeneration of the functions of the two systems is stated to be a difficulty in adaptation of the epicritic type because of the inability of adaptation at its head end or cortex, while the protopathic system can be adapted at its thalamic centers to the regeneration of nerve fibers to wrong end organs. From a logical standpoint this is directly in contradiction to what one might suppose. The book is extremely interesting and worth reading.

Psychotherapie bei organischen Erkrankungen. Von Dr. med. Fritz Mohr, Facharzt für innere und Nervenkrankheiten in Koblenz. Paper. Price, 4.80 marks. Pp. 103. Leipzig: Georg Thieme, 1930.

This small volume is another example of the recent conception of unity of soma and psyche. It is an attempt at better understanding the psychic changes that go along with organic diseases which in themselves may be incurable. The author takes up the special psychotherapeutic methods of modern times and applies them to individual diseases. It is well worth perusal by psychiatrists.

Medicolegal

Malpractice by Examining Physician

(Andrews v. Davis (Me.), 148 Atl. 684)

The plaintiff, a six-year-old child, was struck by an automobile operated by one Bernstein. A fracture of the right leg, near the pelvis, resulted. Bernstein, without consulting the child's parents, engaged the defendant, Davis, to treat her. The parents, however, refused to permit him to do so. The fracture was treated by another physician and a perfect union obtained. Davis, however, told the parents of the injured child that he was employed by Bernstein, by whom the injury was inflicted, or by the insurance company with which Bernstein was insured, to observe the case. From time to time he went to the hospital while the physician in charge of the patient was attending to her needs, claiming that he had the right to be present because of his employment. He took no part, however, in the treatment of the case. Soon after the patient returned to her home, the defendant, Davis, visited her for the purpose of making an examination. While manipulating the injured leg, he caused a new and independent fracture near the knee. It was because of this fracture due to the examination of the patient, and not because of the original injury, that this suit was brought. Judgment was given for the plaintiff, and the defendant appealed to the Supreme Judicial Court of Maine.

Independently of this suit, the injured child brought an action against Bernstein, by whom original injuries were inflicted, damages were assessed and were paid by him, and a release was given of all claims against him. The declaration in the suit against Bernstein did not specifically eliminate nor specifically include the negligence of Davis, the physician employed by Bernstein to observe the injured child while she was under treatment. In the present case, the negligence of the defendant, Davis, was admitted. So also were the injurious results of that negligence. Davis claimed, however, that the judgment given in the suit against his employer, Bernstein, barred the present action. That was the sole issue in this case.

In this case, said the court, the defendant was not "treating" the patient. He had not been employed to treat her, nor did he at any time undertake to do so. He was not acting in her interest; he was examining her in the interest of Bernstein and the insurer of Bernstein, to determine the nature and extent of her injuries and the extent of her recovery from them. He did not aggravate the damage done to the patient by Bernstein; he negligently caused an entirely new and independent injury. For that injury, it was admitted that the patient was entitled to recover damages. The only question was from whom damages should be recovered.

In *Pearl v. West End St. Railway*, 176 Mass. 177, 57 N. E. 339, 49 L. R. A. 826, 79 Am. St. Rep. 302, the question arose as to whether or not damages for an injury caused by the act of an examining surgeon could be recovered from his employer on the ground that the relation of principal and agent existed between them. Chief Justice Holmes, speaking for the court, said:

> The doctor was not an agent or servant of the defendant in making his examination. He was an independent contractor. There is no more distinct calling than that of the doctor, and none in which the employee is more distinctly free from the control or direction of his employer. *See Linton v. Smith, 8 Gray (Mass.) 147; Milligan v. Wedge, 12 Adol. & E.* 737, 741, 742. In this case the doctor was informing himself, according to the suggestions of his own judgment, in order to advise, and perhaps to testify for, the defendant. We must assume, in the absence of other evidence than his profession and his purpose, that what he should do and how he should do it was left wholly to him.

The principle invoked finds support in a long line of decisions dealing with cases not only in which the physician or surgeon was employed to make an examination but also in which he was employed by those responsible for the injury to treat the injured person. If he who is responsible for an injury, without being contractually liable so to do, furnishes gratuitous aid to the injured person, he must use due care in the selection of the physician; but he is not an insurer against such physician's negligence. The relation of master and servant is not created by the employment, unless the employer undertakes to direct the employed physician as to what he shall do and how he shall do it. In the absence of the assumption of such directory power by the employer, the relation of the physician to the injured person is that of an independent contractor, liable for his own torts. Most emphatically is this the case when the arrangement does not include treatment but is limited to examination. The rule finds especially appropriate application when the negligence of the physician results, not in an aggravation of the original injury, but in causing an entirely independent injury, related in no way to the first by any rational line of causation. Such an independent contractor was the defendant in this case. He must answer for his own negligence. The appeal of the defendant from the judgment of the trial court was overruled and the case referred for the assessment of damages.

Evidence: Admissibility of Statements by Patients.—Statements by a patient to his physician, of the patient's bodily ailments, made for the purpose of enabling the physician to give proper medical advice and treatment, may be testified to by the physician, not as evidence of the cause of the ailments but in connection with testimony as to the opinion formed partly on such statements. Mere narration by a patient to his physician of the cause of ailments may not be repeated in evidence. It was competent for the medical witness, after testifying as to the condition of his patient and as to her complaints and symptoms, to give his opinion that they were such as might have been expected from incomplete abortion. Beyond this, what the patient said to the physician was mere hearsay. To the general rule against hearsay, however, there are certain exceptions: dying declarations, declarations called out by the circumstances of a transaction and related to some relevant act, and the declarations of a conspirator, since deceased, during and in furtherance of some criminal enterprise. But a statement by a patient to her physician, that she supposed that if she went back to the man who performed an abortion on her he would take care of her, came within none of these exceptions. Such hearsay was inadmissible.—*State v. Donnell et al. (Maine), 148 Atl. 747.*

Evidence: Failure to Produce Available Medical Evidence.—Counsel for the defendant, in his argument to the jury, commented on the fact that the plaintiff had not produced the roentgenograms which were taken at the hospital and that he had not produced as witnesses two physicians who treated him there. To the rulings of the trial court on his objections to these remarks, plaintiff took exception. He claimed that he did not know the names of the hospital physicians who treated him and that such physicians were just as available to the defendants as they were to him. The production of the roentgenograms was, he said, unnecessary, since he offered other medical evidence of injury to certain of his bones. Moreover, such roentgenograms were public records and were accessible to the defendants under the process of the court. But, said the St. Louis Court of Appeals, Missouri, the burden was on the plaintiff to prove his case, rather than on the defendants to disprove it. So far as the record disclosed, the defendants were not advised that the plaintiff had been treated at the hospital, until he so testified on the witness stand. It would seem to have been incumbent on him, therefore, to seek out the attending physicians and produce them, together with the roentgenograms which they had taken, or else to explain his failure to produce them. In a sense, it was true that, after the patient waived his privilege by his testimony on direct examination, the hospital physicians and roentgenograms were equally available to the defendants, if by equally available it is meant that they were equally subject to process issued at the defendants' request and equally competent to testify and to be put in evidence as a part of the defendants' case. But the term "available" means more than this; it means also that the particular evidence must be equally within the knowledge and power of the opposite party and reasonably expected to be favorable to him. Such was not the case in this instance.

The plaintiff was entitled to pick and choose from the whole of the evidence available to him and to offer only such as seemed wise and expedient to his counsel; but having failed to produce what was peculiarly and particularly within his knowledge and power and what he would naturally have been expected to produce if favorable to him, he was in no position to complain because his adversaries took advantage of his failure and commented to the jury on the inference which the law says was legitimately deducible from that failure.—*Donet v. Prudential Ins. Co. of America et al. (Mo.), 23 S. W. (2d) 1104.*

Evidence: Plaintiff May Testify as to Eyesight.—The appellant contended that the trial court was in error in permitting the appellee to testify that at the time he took out the policy of insurance he had good vision in both of his eyes, that after the accident he had lost the sight in his left eye, and that before the accident he could see out of his left eye as well as he could out of his other eye. Such testimony, the appellant claimed, was made up of mere conclusions of the witness. But, said the Court of Civil Appeals of Texas, Waco, we overrule this proposition. Unquestionably, the appellee had a right to testify that prior to the accident he could see out of his left eye, that after the accident he could not see out of it, and that he had lost the vision in his left eye. These were not conclusions but were statements of facts within the knowledge of the witness.—*Central Texas Mut. Life Assn. v. Parrish (Texas), 23 S. W. (2d) 780.*

COMING MEETINGS

American Academy of Ophthalmology and Otolaryngology, Chicago, October 27-31. Dr. W. P. Wherry, Medical Arts Building, Omaha, Secretary.
American Academy of Physical Therapy, Boston, October 22-24. Dr. Thomas L. Smyth, 111 North Eighth Street, Allentown, Pennsylvania, Secretary.
American Association of Railway Surgeons, Chicago, November 5-7. Dr. Louis J. Mitchell, 29 East Madison Street, Chicago, Secretary.
American Hospital Association, New Orleans, October 20-24. Dr. Bert W. Caldwell, 18 East Division Street, Chicago, Executive Secretary.
American Public Health Association, Fort Worth, Texas, October 27-31. Mr. Homer N. Calver, 370 Seventh Avenue, New York, Executive Secretary.
Central States Pediatric Society, Memphis, Tenn., November 7-8. Dr. A. H. Parmelee, 310 South Michigan Boulevard, Chicago, Secretary.
Interstate Postgraduate Medical Association of North America, Minneapolis, October 20-24. Dr. W. B. Peck, 82 Stephenson Street, Freeport, Ill., Managing Director.
Medical and Surgical Association of the Southwest, El Paso, Texas, November 6-8. Dr. W. Warner Watkins, Box 1587, Phoenix, Ariz., Secretary.
Radiological Society of North America, Los Angeles, December 1-5. Dr. I. S. Trostler, 25 East Washington Street, Chicago, Secretary.
Southern Medical Association, Louisville, Ky., November 11-14. Mr. C. P. Loranz, Empire Building, Birmingham, Ala., Secretary.
Southern Surgical Association, Lexington, Ky., December 9-12. Dr. Robert L. Payne, 142 York Street, Norfolk, Va., Secretary.
Virginia, Medical Society of, Norfolk, October 21-23. Miss Agnes V. Edwards, 104½ West Grace Street, Richmond, Secretary.
Western Surgical Association, Kansas City, Mo., December 11-13. Dr. Frank R. Teachenor, 306 E. Twelfth St., Kansas City, Mo., Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Issues of periodicals are kept on file for a period of five years only. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending, but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

American J. Obstetrics & Gynecology, St. Louis

20: 153-292 (Aug.) 1930

*Chorio-Epithelioma: Disappearance of Primary Uterine Tumor. E. Novak and A. K. Koff, Baltimore.—p. 153.
*Blood Platelets in Pregnancy and Puerperium. P. B. Bland, A. First and L. Goldstein, Philadelphia.—p. 165.
*Results of Investigation and Treatment of Streptococcal Puerperal Sepsis at Toronto General Hospital. W. A. Dafoe, Toronto, Ont.—p. 174.
*Hyperthyroidism Associated with Pregnancy. J. W. Hinton, New York.—p. 183.
*Pregnancy Concomitant with Asthma or Hay-Fever. A. C. Williamson, Pittsburgh.—p. 192.
*Fibromyoma Uteri: Treatment and End-Results. F. E. Keene and R. A. Kimbrough, Jr., Philadelphia.—p. 198.
Fundamental Biochemical Factors in Pregnancy. M. Trumper, Philadelphia.—p. 209.
Progress in Endocrinology of Interest to Gynecologist and Obstetrician. R. T. Frank, New York.—p. 215.
*Frank Test for Female Sex Hormone. H. W. Spencer, New York.—p. 220.
Radical in Obstetrics. J. W. Duncan, Montreal, Quebec.—p. 225.
Surgical Pathology of Fibrinoplastic or Adhesive Variety of Tuberculous Peritonitis. J. W. Kennedy, Philadelphia.—p. 236.
Vesico-Abdominal Fistula as Complication of Labor. H. Acosta-Sison, Manila, P. I.—p. 239.
Walter Channing and Etherization in Childbirth. H. Thoms, New Haven, Conn.—p. 244.
Tuberculosis of Cervix. B. A. Harris, New York.—p. 249.
Purpura Hemorrhagica Complicating Puerperium. H. B. Boley, New York.—p. 252.
Anemia in Pregnancy. J. H. Moore, Grand Forks, N. D.—p. 254.
Fatal Bronchial Obstruction in New Born. P. C. Langan, Akron, Ohio.—p. 255.
Use of Tourniquet for Control of Absorption of Solution of Pituitary in Induction of Labor. S. Hanson, Stockton, Calif.—p. 256.
Director for Vaginal Occlusive Pessary. M. D. Mayer, New York.—p. 258.

Chorio-Epithelioma: Disappearance of Primary Uterine Tumor.—After a discussion of the classification of choriomatous tumors, Novak and Koff consider the disappearance of the primary uterine tumor in cases of chorio-epithelioma. A case is reported in which such a disappearance was noted, although the patient later died of extensive metastases in the brain and lungs. That there was an original primary tumor in the uterus was proved by examination of the uterine curettings several months before the patient's death. Necropsy showed no trace of chorionic tissue in the uterus. Other cases of this type which have been reported are reviewed, and the various explanations discussed. The autopsy showed the ovaries to be the seat of characteristic hyperlutein changes, and gave an opportunity of studying the histology of the pituitary body in relation to these changes.

Blood Platelets in Pregnancy and Puerperium.—The blood platelet count for the nonpregnant woman was found by Bland et al. to vary from 200,000 to 350,000 per cubic millimeter. Platelet determinations were made in 230 women in various stages of gestation, and in 100 of these after delivery. It was found that 177 (77 per cent) of the 230 gravid women had from 200,000 to 350,000 platelets per cubic millimeter of blood, while 42 (18.2 per cent) gave a count of more than 350,000. Therefore it may be stated that the blood platelets are not appreciably increased in pregnancy. Twenty-seven per cent of the 100 women gained over 50,000 platelets per cubic millimeter within twenty-four hours after labor, whereas 63 per cent had either a gain of less than 50,000 platelets or had a lower count than in pregnancy. Counts made three to five days after delivery reveal that 55 women (55 per cent) gained more than 50,000 platelets. Of this number, 35 gained over 100,000 platelets. Fifty-one per cent of the counts made on the group of 100 women from eight to ten days after delivery showed a gain of more than 50,000. Twenty-seven of these 51 women gained from 100,000 to 200,000, whereas 6 gained over 200,000 per cubic millimeter.

Results of Investigation and Treatment of Streptococcal Puerperal Sepsis.—Thirty-two per cent of morbidity in the cases reported by Dafoe were due to puerperal sepsis, and in over 50 per cent of these, *Streptococcus hemolyticus* was the causative organism. *Streptococcus hemolyticus* was found to be seasonal in appearance and occasionally present in the genital tract during pregnancy, more often during labor, and most often in the puerperium. Dafoe emphasizes the fact that *Streptococcus hemolyticus* when found in the cervical canal during the puerperium is always a source of danger. Early investigation and immediate treatment of puerperal sepsis cases is essential. Scarlet fever antitoxin has a special value in the treatment of puerperal and postabortal cases of sepsis due to *Streptococcus hemolyticus.*

Hyperthyroidism Associated with Pregnancy.—In Hinton's opinion the two types of cases which need pregnancy interrupted are chronic hyperthyroidism associated with the nodular or adenomatous goiter in which there is a definite myocardial degeneration, and cases of exophthalmic goiter which are of a fulminating type and which endanger the life of the mother by allowing the pregnancy to continue. He estimates that 90 per cent of cases of hyperthyroidism associated with pregnancy can be carried to a normal delivery if properly managed.

Pregnancy Concomitant with Asthma or Hay-Fever.—Williamson reports a group of twenty-seven cases. The asthmatic group bears out almost to a patient the part played by heredity in transmitting the tendency to the disease. In no case was it known that the husband was affected, and yet practically every child showed an eczema or an idiosyncrasy toward food. As far as severity of attacks go, apparently asthmatic persons, as such, seem to have less frequent attacks during the period of gestation and puerperium. A most striking observation is that the attacks with all their paroxysmal sneezings and coughings together with the unpleasant dyspnea do not seem to bring on premature labors or miscarriages. Skin testing has been rather disappointing. It is curious to note that the same mother during gestation with a male child would be free from the discomfort of urticaria or "food poisonings" and yet be most sensitive if pregnant with a female child or vice versa. Equally strange is the fact, too, that one sex would have eczema and no food difficulty while the other sex would have both. It would also seem that there is no reason why the mother should not be treated as though she were not pregnant.

Treatment and End-Results in Fibromyoma Uteri.—Keene and Kimbrough present an analytic study of 254 consecutive cases of myoma uteri. The results following hysterectomy were satisfactory in 92.5 per cent. Lumbar or sacral backache was noted in fifty-five cases before operation. Of these patients, 49.1 per cent were relieved, 23.6 per cent improved, and in 27.2 per cent there was no improvement so far as backache was concerned. In the entire series four deaths occurred, a total mortality of 1.57 per cent. There were no deaths after irradiation, thus making the operative mortality 2.15 per cent. Pulmonary embolism was the cause of death in three patients, and autopsy proved the fourth to be due to massive atelectasis of the lower lobes of both lungs, associated with chronic myocarditis. The deaths from embolus occurred on the sixth, eleventh and fourteenth postoperative days, respectively. Each of these patients had large tumors and, in two, hysterectomy was extremely difficult because of their intraligamentous position. Radium was employed in 21.3 per cent with satisfactory results in 93.7 per cent. Roentgen irradiation was the method of choice in 4.7 per cent, and the results were uniformly good. There were no deaths following irradiation.

Frank Test for Female Sex Hormone.—Frank's test for the female sex hormone in the blood was done by Spencer in a series of twenty-one cases. Twelve of these patients complained chiefly of sterility, with or without menstrual irregularities. Four complained of amenorrhea varying from two months to seven years in duration. Three pregnant and two normal women were tested as controls. The blood of the normal women gave positive reactions preceding menstruation and negative reactions following it. The pregnant cases, in the sixth month or later, invariably gave strongly positive reactions. This is in accord with Frank's observations. In the cases of sterility and amenorrhea there was a great variation in the results obtained. There were five cases of sterility with regular menstruation. Three of these patients gave negative reactions to repeated tests. One later proved to be four weeks pregnant at the time the test was made. One gave a positive test preceding menstruation; another was positive only after the flow. There were four cases of sterility with irregular menstruation. Of these, two gave negative reactions to each test; one was positive before the flow; one gave a slightly positive reaction both before and after the flow. Of the patients with amenorrhea, one with a strongly positive reaction was eight weeks pregnant. Two had definite cycles when a positive reaction was obtained, although negative at other times. One gave a slightly positive reaction on one test. Three gave negative reactions whenever tested. Stimulating roentgen therapy was tried in three cases, with slight improvement in two but with no change in the third.

Streptothricosis.—A case of streptothricosis, possibly primary in the lungs, is reported by Singer and Ballon. Streptothrix was found clinically in the gums, sputum, pus from superficial abscesses and, at necropsy, in practically every organ of the body. The signs and symptoms of the disease in this instance were fever, moderate leukocytosis, and those referable to the different organs involved. Thus, at first, they were of a nephritis, later of a bone disease, and last of a widespread involvement of the lungs, ribs and chest wall. Throughout the illness there was a persistent but quite unexplained purpura. Treatment in this instance consisted of potassium iodide by mouth. Massive doses were given until the signs of iodism were produced. The patient also received several injections of iodized oil by the aspiration method. The abscesses of the chest wall were incised and drained. Pathologically the lesion in the lung was associated with pulmonary tuberculosis. Tubercle bacilli could be demonstrated from direct smear in pus obtained from the abscess cavities. At no time during the course of the disease could tubercle bacilli be demonstrated in the sputum. The frequent occurrence of gram-positive nonacid-fast anaerobic streptothrix with tubercle bacilli in the sputum of patients with pulmonary tuberculosis has been noted by one investigator. Such streptothrices were nonpathogenic for guinea-pigs. Others have also noted the association of tuberculosis and streptothricosis. It would seem that the important consideration is that the organism must be pathogenic for guinea-pigs. The lesions in the lung showed the characteristic nodular formation with necrosis and abscess formation. There were few proliferative changes and consequently little or no evidence of bronchiectasis.

Relation of Anatomic Variations to Physical Diagnosis.—A case of an accessory lobe (azygos lobe) of the upper lobe of the right lung is reported by Mackmull. The physical signs incident to this anomaly resembled those of pulmonary tuberculosis.

Studies of Heart in Tuberculosis.—Studies of electrocardiograms and roentgen plates have been made by King and Hansen in 100 unselected cases of tuberculosis. The diameter of the heart was found to be lower in this series than in normal individuals, as reported by Groedel and by Norris and Landis. The average weight of the heart in this series is on the whole lower than in the nontuberculous, as recorded by various observers. Nearly one third of this group had a cardiothoracic index below 40 per cent, as compared with one-fifth (21 per cent) in the normal. Low voltage of the Q-R-S complex in one or more leads occurred sixty times in the series. Of these sixty cases, 21 per cent were found in lead 1, 27 per cent in lead 3, and 12 per cent in leads 1 and 2, as compared with 8 per cent, 38 per cent and 1 per cent in the nontuberculous.

Influence of Pulmonary Collapse on Electrocardiogram.—Electrocardiograms have been studied by Hansen and King in sixty-six patients who have undergone seventy-three pulmonary collapse procedures (pneumothorax, phrenic exeresis, thoracoplasty), analyzing the conditions found before and after collapse. These procedures are almost invariably followed by changes in amplitude of the electrocardiographic waves, R wave modification occurring in 96 per cent of the cases, but the type and degree of variation is not constant or predictable, according either to the side involved or to the procedure carried out. Evidence suggests that the changes are due to changes in heart position, influenced largely by pleural and mediastinal adhesions, more than by myocardial factors.

Piedra.—A description of piedra is given by Aars, based on sixty cases observed in Dutch Guiana. The condition is frequently encountered in Paramaribo; it occurs in men more often than in women. Though the occurrence of piedra is common in Dutch Guiana, the condition is of little importance from the point of view of the patient. The fungus is not a true ectothrix; in many cases the cuticle of the hair was seen to be damaged by the parasite. The disease involves only the shaft of the hair, not the root. The infectiousness of the fungus is slight. Therapy is simple. In severe infections, it is advisable to cut off the hairs entirely; good results can be obtained by applying macerating antiseptic lotions and by combing the hair regularly with a fine comb.

Cavernous Hemangioma and Trauma.—A case is presented by Downing and Mallory which is considered as a true hemangio-endothelioblastoma occurring after trauma. While the patient was riding in a wagon during October, 1918, a shell exploded nearby, killing the horses and rendering him unconscious. He regained consciousness and found his neck, face and shoulders bandaged. When the dressings were removed, the left side of his face, neck and shoulder was covered with crusts and serous fluid. About three months after the injury, the patient noticed a deep swelling on the left side of the neck. This swelling continued to increase in size. Gradually red and blue spots and nodular swellings began to appear all over the injured area.

Value of Bismarsen in Treatment for Syphilis.—Shivers has made a careful study of 152 patients suffering from all types of syphilis who were placed on bismarsen therapy. The use of twenty injections of neoarsphenamine of 0.6 Gm. each and twenty injections of potassium bismuth tartrate of 0.1 Gm. each was more efficient than bismarsen alone in sterilizing patients who have early syphilis. Therefore, in this stage the latter drug should be used only as a second course; thus a larger percentage of patients will be completely sterilized and at the same time complications which frequently occur during the second course of intravenous treatment will be avoided. Those in whom bismarsen may be the only drug used for early syphilis are old people, debilitated persons and patients in whom syphilis is complicated by another disease. In late syphilis, bismarsen is more frequently the drug of choice when one wishes to administer arsenic and bismuth, as the reactions are much fewer and consequently the danger less. The clinical improvement and effect on the Wassermann reaction have been very favorable. The clinical effect of this drug in cerebrospinal syphilis, especially of the acute meningeal type, has been most striking.

Response of Serologic Tests to Treatment.—In a study made by Gilman and McIntyre of 105 cases of syphilis comprising both early and latent types in patients under treatment, involving 910 serologic tests in duplicate, the initial agreement between the Kolmer-Wassermann test and the Kahn precipitation test was 91.4 per cent and the disagreement was 8.6 per cent. In the 83 cases comprising the group of patients with untreated early syphilis, the agreement was 95.2 per cent, and included in this was the 100 per cent agreement between the tests in cases of untreated secondary syphilis. In the 22 cases of latent syphilis before treatment there was 77.2 per cent agreement and 22.8 per cent disagreement. In 9 cases of syphilis in which there was disagreement between the two tests, the Kolmer-Wassermann test was positive in seven, and the Kahn precipitation test was positive in two. Subsequent comparison of the two tests during treatment showed in the aggregate a close agreement throughout observation. Although the Kolmer-Wassermann test was found to be more sensitive in untreated syphilis, either test alone furnishes adequate serologic control during treatment.

Clinical Excretion of Bismuth.—Hanzlik et al. found that the clinical excretion of bismuth after the intramuscular injection of bismuth metal in doses of from 0.15 to 2.1 Gm. was found to be slow, irregular, prolonged and incomplete. The daily excretion fluctuated considerably in different subjects, being characterized by a gradual increase, which reached a peak or maximum in from six to twenty-eight days after administration, the time increasing proportionately with the dosage and a gradual decrease occurring until the output reached about 0.5 mg. a day. The duration of excretion after two or more single doses persisted for at least three months, thus agreeing generally with roentgen studies of muscle depots. The maximum daily excretion increased out of proportion to the increase in dosage in different subjects, indicating that accumulation of bismuth in the tissues would not necessarily increase in proportion to dosage. The desirability of using small repeated doses instead of intensive medication for maintaining a uniform saturation of the tissues in the treatment for syphilis is suggested. The total urinary excretion was extremely variable and comparatively small. In the three subjects in whom this was definitely ascertained, it amounted to 0.4, 54.6 and 31.3 per cent, respectively, of the total doses administered; namely, 0.15, 0.6 and 1.2 Gm. The total excretion decreased with increasing doses in different subjects, according to the percentage of the total administered and also absolute amounts during comparable periods. This decrease was not due to escape of bismuth into the feces, since the excretion in feces was too small over a considerable range of dosage in different persons. The median excretion in urine was about eight times that in the feces, thus indicating that the kidney was the main organ of excretion, a result which correlates with the high selectivity of bismuth for this organ. The bismuth unaccounted for remains in part as a depot at the site of injection, from which it is slowly liberated, a part of the latter being stored in viscera and the whole being excreted from the body slowly in traces over periods of months. Contrary to impressions from roentgen studies of muscle depots, the results obtained show that bismuth metal injected intramuscularly is absorbed, since traces of bismuth in urine are demonstrable on the day following injection, the quantities being definite on the second to third day, and bismuth persisting in urine during at least three months after two or more single doses of 0.15 Gm. It is undesirable to attempt rapid saturation with high doses, since total doses of from 0.6 to 2.1 Gm. of bismuth metal tend to decrease the absolute total output despite a tendency to increased maximum daily output out of proportion to the increase in dosage.

Pulmonary Siderosis.—Two cases of pulmonary siderosis are reported by Bohrod. One, in which the dust was metallic iron, produced the black variety of siderosis and ended in a florid tuberculous bronchopneumonia. One, in which the dust was iron ore, produced the siderosis of the red variety and the concomitant tuberculosis of the fibrotic type and limited to the lymph glands. In both cases there was a continuous attempt at excretion of the iron by macrophages which carried it into the alveoli and thence into the sputum, by excretion through the bronchiolar mucosa or by transference to the lymph nodes. In the last event, the pigment was either deposited in the gland or was carried through the gland and reached the blood stream probably by way of the thoracic duct. Having reached the blood stream, the iron was deposited in the cells of the reticulo-endothelial system. In addition to transportation, there was gradual transformation of the iron. Only the soluble iron could be transported and was found intracellularly. In the black variety, in which more silicon than iron was present in the lung, only the more soluble iron found its way into the blood stream. Insoluble iron was found extracellularly in dense fibrous tissue. Where the accumulations of iron were greatest, the amounts present were 8.9 and 7.9 per cent of the moist weight of the lungs.

Giant Cells of Benign Giant Cell Tumors of Bone.—On microscopic examination of giant cells from eleven specimens of benign giant cell tumors of bone, Johnson has found that giant cells are most numerous where the vascular tissue is most abundant; that giant cells form a portion of the lining of blood vascular spaces; that there is no break in continuity between early giant cells and the endothelial lining of the vascular spaces; that the giant cells lie in immediate contact with living blood elements without the interposition of an endothelial lining; that excavations or hollows in the giant cells communicate directly with the lumen of blood vessels, and that the "holes" seen frequently in the body of a giant cell are in reality the lumen of newly formed blood vessels, many of them being filled with blood. These observations show that the giant cells of benign giant cell tumors of bone arise from the endothelium of the blood capillaries.

Congenital Atresia of Tricuspid Orifice.—The postmortem examination of an infant, aged 8½ months, disclosed congenital atresia of the tricuspid orifice of the heart associated with defects of the interauricular septum, hypoplasia of the right ventricle and a subaortic defect of the interventricular septum. Breslich says that the most important symptom of this lesion clinically was cyanosis, increased by slight exertion, with an associated loud systolic murmur of the heart heard over the entire precordium. The developmental defects of the heart were similar to those which Kühne and Wieland described as simple tricuspid atresias, of which about thirteen cases have been recorded.

*Tuberculosis: I. Allergic, Anaphylactic and Immune Reactions in Guinea-Pigs Following Inoculation with Heat-Killed Tubercle Bacilli. A. Branch and J. R. Cuff, Boston.—p. 151.

Survival of Paratyphoid Bacilli in Foodstuffs.—Experiments were made by Doyle regarding the persistence of agglutinogens in certain canned vegetables that had been inoculated with strains of bacilli of the paratyphoid-enteritidis group. Moreover, an attempt was made to obtain some information as to how long the bacilli themselves may live when they are introduced into canned foods. He found that the length of time for which paratyphoid bacilli lived after being introduced into certain canned vegetables varied within wide limits. *S. aertrycke* remained alive in canned spinach for three years. *S. aertrycke* and *S. enteritidis* agglutinogens were easily demonstrated in unheated corn, spinach and peas three years after inoculation. *S. aertrycke* agglutinogens were clearly demonstrable in the vegetables after being heated. Relatively slight heating apparently destroyed or greatly reduced the enteritidis agglutinogens.

Influence of Complement on Sensitiveness of Complement-Fixation Tests for Syphilis.—Havens and Frank assert that tests of 1,066 serums, the unit of complement obtained by titration with serum and antigen being used, yielded 45 positive results which were negative with the standard test. Agreement between the complement-fixation test, the serum unit being used, and the Kahn precipitation test was 99.4 per cent, as compared with 95 per cent agreement when the standard Kolmer test with the full unit of complement was used. In 106 treated patients with syphilis, 29 positive results were obtained with the standard test, 61 with the serum unit and 65 with the Kahn precipitation test.

Allergic Reactions in Guinea-Pigs Following Inoculation with Heat-Killed Tubercle Bacilli.—Branch and Cuff used the guinea-pig as the experimental animal and tubercle bacilli from man (strain H 37, Saranac Lake) as the bacterial antigen. Allergy and anaphylaxis in tuberculosis are independent phenomena, and immunity may be present without allergy. Intramuscular inoculation with heat-killed tubercle bacilli (and probably also intravascular inoculation) produces immunity and anaphylaxis without allergy, whereas intraperitoneal and intrapleural inoculation produces allergy, anaphylaxis and immunity. The development of allergy appears to be interrelated with the process of caseation. The practicability of prophylactic immunization of children by intramuscular inoculation with heat-killed virulent tubercle bacilli is suggested, the advantage being that if immunity can be obtained without allergy the valuable tuberculin skin test, if later positive, is evidence of infection and not the result of the vaccination.

Ambrose Paré—Military Surgeon. H. E. Hullsiek, St. Paul.—p. 648.
Hyperthyroidism. E. G. McLane, Sleepy Eye.—p. 652.

Clinical Aspects of Sclerotic Changes in Aortic Valve.—The four cases reported by Drake were all in elderly individuals none of whom had a rheumatic history or (except a slight thickening of the mitral valve in one case) a demonstrable lesion in any but the aortic valve. In all four cases, stenosis of the aortic valve was the predominating lesion. A striking feature was the absence of a systolic thrill in any of the cases reported. This was probably due to an insufficient velocity of the blood stream as a result of a weak myocardium. Although the aortic valve was doubtless insufficient in some of the cases reported, no diastolic murmur was heard in any of the cases. This was doubtless due to the accompanying stenosis, which prevented an elevation of the systolic blood pressure and thus the pressure and velocity of the return blood flow through the aortic valve was insufficient to produce a murmur. The pulse pressure in all four cases was within normal limits in spite of regurgitation undoubtedly being present in at least some of these cases. The only explanation of this phenomenon is that, the greater the stenosis, the less the regurgitation possible, and the regurgitation is not sufficient to affect the pulse pressure noticeably. Systolic murmurs heard over the mitral region and transmitted to the axilla were not due to demonstrable lesions in the mitral valve. While they may have been caused by a relative mitral insufficiency, they were probably the transmission of the murmur produced by the stenosed aortic valve. Atheroma of the aorta was not a prominent feature in these cases, although there was evidence of marked arteriosclerosis elsewhere in every case reported.

Status of Tinted Lenses.—The prescribing of tinted lenses for the apparently healthy eye without tangible and sufficient reason for so doing is condemned by Fink. It is not only unscientific but in many cases positively contraindicated. When one stops to realize that under ordinary circumstances the sound eye needs no protection against ultraviolet rays and that the tinted lens cuts down the visible rays from 15 to 35 per cent or more, depending on the shade, it is inconceivable that a tint without full and sufficient reason should be prescribed. The retina is stimulated into activity by visible rays. Any means that lessen this stimulus interfere with the perceptive apparatus to some extent. It is true that certain individuals with apparently sound eyes are made miserable in ordinary sunlight. These individuals may be pathologically affected, in that adaptation is slow or that adaptation, when once effected, is below normal, or they may in reality be mentally or physically abnormal. Often in physical diseases or neurasthenia the general function of the eye is impaired, and in this type of patient help is needed. Where the glare exists in moderate amount, attention should be directed to the lighting arrangement and hygienic measures before the easier method of tinted lenses is employed. If this were done, many cases of asthenopia attributed to light effects would be cured without cutting down the luminous spectrum. In the myopic eye a tinted lens is more often needed. Here it is advisable to use a soft tint to cut down the sharpness of the image. Ophthalmologists should not be misled by advertising claims of optical houses that seek to popularize the routine prescribing of absorptive lenses, but should consider the absorptive glass as a therapeutic procedure to be used when indicated, and realize that it can be just as harmful to certain eyes as it can be helpful to others.

Primary Carcinoma of Lung.—The most constant symptoms in the series of eighteen cases reported by Fremont-Smith et al. were dyspnea and cough, noted in sixteen and fourteen instances, respectively. Chest pain was present in twelve patients. Sputum was specifically mentioned in the records as present in twelve cases. In six the sputum was frankly bloody, in the remaining six, streaked with blood. "Currant jelly" sputum was not observed. Definite clubbing of the fingers was noted in five instances. Five patients were afebrile while in the hospital wards. All the others had more or less fever. In one case with an unusually malignant tumor, a few days of fever alternated with short periods of normal temperature over several weeks. Anemia was frequently present but usually slight. The blood pressure was consistently low, in view of the ages of the patients. Pleural effusion was demonstrated clinically in eight cases. The effusion was clear or turbid in five and sanguineous in three. They assert that, in a man past middle age, onset of pain in the chest, dyspnea or hemoptysis should lead to the suspicion of pulmonary neoplasm. The onset of symptoms may be insidious or fairly acute. A period of declining health and loss of body weight may or may not precede the pulmonary symptoms. The first symptoms recognized by the patient may be due to metastases. A unilateral, sharply defined area of dulness and diminished breathing, suggestive of encapsulated fluid, may be due to cancer of the lung. Early in the disease, examination of the chest may be negative.

Problems of Medical Service.—The growth of industrial medicine and discussion of the possibilities of some form of sickness insurance in this country, Rappleye says, require that all those interested in medical care shall keep clearly in mind that the most important factor in a sound medical service is the quality of medical care, not the scheme of organization or the method of financing. There are features of finance, problems of organization and interests of the public in this problem of medical care, but the essential character of it is professional and technical. The quality, interpretation and correlation of scientific knowledge depend on trained personnel who know the significance of that knowledge and how to use it. He concludes: There are two outstanding trends of our age, the democratic and the scientific. The hope of democracy depends on leadership. We look for such leadership in law, education, business and banking and there is no reason why the public should not expect it of medicine. We possess the knowledge and personnel to solve a large national problem and possessing that knowledge, we are responsible for working out a satisfactory solution. We cannot hope to enjoy the leadership to which we are rightly entitled in modern society by constant opposition to proposals intended to deal with medical problems, even when those proposals are vague and obviously unsatisfactory or when proposed by those unfamiliar with the essential character of the problem. What we need is a constructive and sustained program directed and supported by the best brains of the medical profession which will aim to provide, control and retain leadership in health matters and in the program of medical services through proper organization of the profession, sound schemes of medical and postgraduate education and wise constructive public policy and publicity. That is the challenge to the organized medical profession in this country which can be met only by wise, far-seeing unselfish, constructive leadership.

Thyroid in Pregnancy.—Reycraft asserts that at least 30 per cent of Ohio women in the child-bearing age normally have thyroid enlargement. Over 50 per cent of pregnant women show thyroid enlargement and some of these will sooner or later show symptoms of toxic goiter. Routine prophylactic treatment instituted early in pregnancy is recommended. Hyperthyroidism in the pregnant woman can be treated medically and surgically without danger to the fetus, and seldom, if ever, is therapeutic abortion indicated because of this complication.

Trichomonas Vaginalis.—Faulkner has found *Trichomonas vaginalis* in certain cases of resistant leukorrhea: 1. In seven patients with long standing recurrent leukorrhea and normal cervices. Some of these had been treated for months by ordinary methods with temporary relief, but not cured. One had been made worse by cauterizing the cervix. 2. In one patient with a leukorrhea, who had had a panhysterectomy two years before. 3. In two young unmarried women with discharges troublesome only after menstruation. 4. In two patients with irritating leukorrhea after the menopause. 5. In one patient with a foul leukorrhea during pregnancy. 6. In a final patient who had an exacerbation of leukorrhea without gonococci, four months after a gonorrheal infection was pronounced cured. In this case perhaps the normal vaginal flora was thrown out of order by the preceding gonorrheal infection and treatment therefor. All of these patients were relieved of symptoms by treatment with 10 per cent aqueous solution of methylene blue (methylthionine chloride U. S. P.) applied freely to the vagina and a boroglyceride pack. Lactic acid douches, 1 or 2 per cent, restore the normal vaginal flora. The patient is cautioned to avoid contamination of the genital tract after bowel movements.

Mercurochrome-220 Soluble as Vaginal Antiseptic in Obstetrics.—A comparative study made by Mayes and Ullian of the bacterial flora of the birth canal with and without the use of mercurochrome as a vaginal antiseptic showed that the number of positive cultures from the vagina was reduced from 44 per cent to 6 per cent; from the cervix, 16 per cent to 4 per cent; from the membranes, 32 per cent to 6.4 per cent. Positive cultures were obtained in twenty-six different patients and in only one instance was there a positive vaginal and cervical culture in the same patient. More positive cultures were obtained in primiparas than in multiparas. Of thirty cultures taken from eleven patients who had only vaginal examinations, one was positive. The cases with the vaginal and rectal examinations showed the most pathogens. The number of pathogens in the vaginal cultures increased with the duration of labor, while with the cultures from the cervix and membranes this did not obtain. With ruptured membranes the positive vaginal cultures increased up to eighteen hours of labor, but in thirty-six cases in labor over eighteen hours only one positive culture was obtained from the vagina and two from the cervix. In thirty-four cultures when the membranes were ruptured over twelve hours, one positive pathogen was found. If the patients were instilled at the time of delivery, 18.18 per cent showed pathogenic organisms in the vaginal cultures, while fifty-two patients who had the mercurochrome in the vagina less than three hours were all considered negative. There were more than twice as many positive vaginal cultures obtained in the operative than in the spontaneous deliveries. With the cervical cultures there were less in the operative. In a control series of twenty-five cases in which no mercurochrome was used, seven times as many positive vaginal cultures were obtained, four times as many from the cervix and five times as many from the membranes. The morbidity was three times that of the year 1928. Nine cultures taken from the interior of the uterus at cesarean section were all negative. These results undoubtedly prove that mercurochrome does reduce the bacterial content of the birth canal during labor, and even though the membranes are ruptured and labor prolonged, if the mercurochrome is instilled regularly and properly the number of pathogens apparently does not increase either in the cervix or in the membranes.

Elimination of Pain in Obliterative Vascular Disease of Lower Extremity.—Smithwick and White assert that it is rarely necessary to amputate an extremity because of pain, and furthermore that extremities which hitherto have been undoubtedly doomed to amputation because of indolent, sensitive, painful ulcerations can often be saved if the pain factor is eliminated for a sufficient length of time to give conservative procedures a chance to take effect. It should never be necessary to amputate an extremity unless it is hopelessly gangrenous or unless intervening sepsis threatens the life of the patient. Pain in the lower legs and feet secondary to obliterative vascular disease can be relieved by alcohol injection of peripheral nerves. This can be accomplished without paralysis of any important muscles of the leg or foot. Careful operative technic and scrupulous asepsis are essential to success. A serious slough may be precipitated by spilling alcohol into the tissues. Incisions should be made above the lower third of the leg and should be vertical by preference. They usually heal by first intention. Depending on the length of nerve trunk injected, the anesthesia produced may last but a few months or may be permanent. After an extremity has been desensitized by this method they have noticed frequently that the foot becomes drier and warmer and that previous color changes are eliminated. The surface temperature may rise 5 degrees F. This is probably due to elimination of sympathetic stimulation both by relieving pain and by interrupting the course of the nerve fibers to their peripheral destinations. The majority of the sympathetic nerves course peripherally with the sensory nerves. The result is much more apt to be successful if the popliteal artery pulsates. In cases of senile arteriosclerosis with arterial obliteration above the popliteal vessel, this procedure, even if done in two or three stages, may precipitate actual gangrene and hasten amputation. They feel, however, that, in such a case if amputation is necessary anyway because of pain, one is justified in desensitizing the extremity first. After an extremity has been desensitized, ulcerations that previously resisted all methods of treatment will frequently heal.

Treatment of Irreducible Intussusceptions in Children.—Two young children with definite irreducible intussusceptions were successfully treated by Montgomery and Mussil by fixing the irreducible part in position by a row of silk sutures placed about the neck and short circuiting this obstructed portion by a local anastomosis. The rationale of this method of treating irreducible intussusceptions would seem to be supported by the results of experimental work done on dogs.

Structural Basis of Traumatic Epilepsy and Results of Radical Operation.—Twelve cases reported by Foerster and Penfield provide an opportunity for studying the result of the excision of cerebral cicatrix in epileptic patients and the mechanism involved. The gunshot wounds of the brain were of long duration and the birth injuries of still longer. Consequently the excised tissue offered a remarkable opportunity to study the late results of cerebral trauma histologically. In each of the twelve cases there was displacement of one or all of the ventricles toward the side of the lesion. In most of the cases there was some degree of enlargement of the ventricle on the side of the lesion. In the two cases of birth injury the enlargement was enormous. That the local atrophy is not the cause of the deflection of the ventricles toward the site of the lesion is shown by the fact that the wandering of the ventricles is not greater in those cases in which the atrophy is great. Likewise cases of cerebral thrombosis do not show this ventricular displacement and many cases with little or no enlargement of the lateral ventricle may show quite marked ventricular displacement. Instead of wandering of the ventricles, the process is really brain pull or ventricle pull. It seems evident that cicatricial contraction is responsible for the displacement of the ventricles in these human cases, as has already been demonstrated experimentally. Histologic examination of this human material provides eloquent evidence of a long-continued cicatricial traction. There was always fibrous tissue, especially near the surface, and adhesion to the meninges. Thus connective tissue and an astonishingly rich plexus of vessels were invariably present in the scars, intermingled with fibrous astrocytes whose fibers were in general arranged in parallel and extended in the direction of the obvious traction; that is, upward toward the cicatrix. Deeper down in the brain the astrocytes and blood vessels still continue to form the only framework capable of withstanding tension, the vaso-astral framework. In the areas of gliosis, nerve fibers are rare and nerve cells still rarer. Occasionally localized areas are found in which there are groups of phagocytes containing pigment. Such patches are evidently in the vicinity of blood vessels which have been shut off and they seem to indicate that the process of cerebral destruction is a long-continued one as they were present twelve and fourteen years after the initial wound. These areas recall the focal perivascular destruction described by Spielmeyer in epilepsy of a different type. The most extreme degree of progressive scarring is seen in the two cases of birth injury, both of which were of nineteen years' standing. In these cases the process of connective tissue invasion and fibrillation of neuroglia had gone to such a point that there were tubes and sheets of neuroglia surrounded by connective tissue sheaths. Even when local atrophy and destruction had given rise to the presence of cysts there was always to be found also an area of gray, gelatinous fibrous tissue, the center or the focus of concentric traction. One further convincing evidence of the physical pull which these scars exert is the fact that in one of these cases reported and in a number of others observed by the authors there was a definite pulling in of the scar which was noted as soon as the bone was removed and the edges of the adherent dura incised. The center of the scar thus drew itself together, sucking the attached dura inward as much as 1.5 cm. as soon as it was freed from the attachment to the overlying skull. In the twelve cases the time between the wound and the onset of convulsion varies between five months and fourteen years, the average period of immunity before the onset of attacks being five years and six months. The acute effect of the injury must have disappeared long before the end of the fifth year. There remains, however, one process progressive through all these years, and that is the cicatricial contraction which gradually draws one or both hemispheres toward the lesion. The authors show that at operation the focal epileptic attacks may often be produced in two ways: either by electrical stimulation of the brain in the neighborhood of the wound, or by gently pulling on the adherent dura. The latter fact may be of considerable significance, for if increase of a preexisting strain produces an attack it may well be that the preexisting strain itself is an important factor in the etiology of spontaneous convulsions. It is pointed out that the blood vessels form in one sense the woof of the contracting network. Traction, therefore, on the vessels must be inevitable. The hypothesis at once suggests itself that a vasomotor reflex secondary to this traction is responsible for the initiation of the convulsive seizures.

Study of Tumors Involving Occipital Lobe.—The clinical features of forty cases of tumor of the occipital lobe are reviewed by Allen, and their frequency, pathogenesis and significance discussed. The initial symptoms were epileptiform attacks in 30 per cent, a visual aura or visual hallucinations in 12.5 per cent, general mental impairment in 17 per cent, headache in 35 per cent, transient or progressive failure of vision in 15 per cent, and strabismus in 2.5 per cent. In only 12.5 per cent did the initial symptoms suggest that the visual paths were involved. The relative frequency of different symptoms of tumor of the occipital lobe was: visual hallucinations, 25 per cent; symptoms suggesting abnormality of the visual fields, 16 per cent; epileptiform attacks, 52.5 per cent; auditory hallucinations, 5 per cent; abnormal tastes and smells, 12.5 per cent; headache, 95 per cent; diplopia, 22 per cent; impairment of vision, 57 per cent; disturbances of speech, 35 per cent; spontaneous subjective sensations, 30 per cent; disturbances of motor functions, 52 per cent; and mental symptoms, 55 per cent. Important conditions found on examination of the patient were: mental changes, 60 per cent; contralateral homonymous defects of the visual fields, 94 per cent; papilledema or optic atrophy, 70 per cent; inequality of the pupils, 35 per cent (contralateral pupil the larger in 25 per cent); ocular pareses, usually of the external recti, 30 per cent; nystagmus and nystagmoid jerkings, 35 per cent; disturbances of speech functions, 30 per cent (50 per cent of left-sided tumors); disturbances of sensation of the suprathalamic type, 55 per cent; and minor degrees of motor disturbance usually in the contralateral limbs, 90 per cent. The changes in the visual fields found in the majority of cases occurred only in the contralateral halves of the fields. In individual cases the visual fields showed: (*a*) complete hemianopia up to the fixation point; (*b*) incomplete hemianopia with spacing of the field for central vision; (*c*) quadrantic defects; (*d*) peripheral crescentic defects, and (*e*) no abnormal changes. When vision was failing, a concentric contraction of the visual fields was sometimes found added to the foregoing variations. In the majority of cases, symptoms of increased intracranial pressure dominated the clinical picture from the beginning; in a few, epileptiform attacks occurred for some time; and in others there was a history of exacerbations of increased intracranial pressure for as long as two years.

Use of Radon Seeds in Treatment of Carcinoma.—Eighty-five cases have been treated with radium by Souttar. Of eleven skin cases the tumor has disappeared in all, and there has been no recurrence, local or otherwise, after periods extending up to seventeen months. In the lip cases in every instance there was a rapid local response, and three out of the five patients have remained well for six, thirteen and fifteen months. The one fatal case was untreatable when first seen.

The tongue cases were all advanced cases, untreatable by any other method. In every instance, however, there was a rapid local response, with, in every case but one, a total disappearance of the primary tumor. In the four cases in which the glands were treated by radium, they responded at once. In five of the seven cases distant secondary deposits appeared, and in only one was there any possibility of a permanent cure. This also was, however, a totally inoperable case. The six mouth cases were all entirely inoperable, five of a very advanced and extensive nature. In the only case in which the growth was limited, although surgically inoperable, there has been no recurrence after two years. In four of the other cases the local growth disappeared but recurred later. Twenty-four breast cases are classed as early, advanced but operable, and inoperable. Of the eleven patients in the first group all but one have been followed to date, and these all remain free from recurrence at periods of from six to twelve months. The twenty-six cases of carcinoma of the esophagus show beyond question that in a large proportion of cases swallowing can be achieved by means of radium, giving relief for periods up to fourteen months.

Pernicious Anemia and Blood Transfusion.—Don asserts that severe cases of pernicious anemia with an elevated temperature often respond well to a blood transfusion, and in some cases it is probably a life-saving measure. Improvement takes place more quickly if arsenic is prescribed for patients who are under liver treatment. It is safer not to rely entirely on liver extracts. Whole liver should always be included in the diet in every case of pernicious anemia.

Acute Lymphocytic Leukemia.—Pearce reports a case in a girl, aged 8, in which recovery ensued after intramuscular injections of hog spleen.

Right-Sided Visceroptosis.—Fifty-one cases are analyzed by Hemsley. He concludes that right-sided visceroptosis is due to the persistence of the embryonic mesentery of the ascending colon. The degree of ptosis depends on the shape of the patient's abdomen, the length of the mesentery and the presence of abnormal bands and membranes. The symptoms are caused by traction on the mesenteries and stimulation of the sympathetic nerves, resulting in inhibition of the normal intestinal movements. Traction may be so concentrated by abnormal bands or membranes as to cause local injury to organs by interference with their vascular, lymphatic and nerve supplies. Waugh's colopexy or some modification of it gives satisfactory results in the treatment of right-sided ptosis. Early recognition and treatment of this condition will prevent the development of many serious abdominal lesions.

Mortality of Acute Appendicitis.—Miller's review of the causes of mortality in appendicitis shows that more than 200 of the 239 patients discussed died primarily from peritonitis or sepsis or toxemia or from a combination of the three conditions. The majority of the remainder died from functional disease on which appendical disease was superimposed, cardiorenal complications being particularly important factors in patients over 50. No matter what the actual cause of death, however, the fact remains that it was appendical disease or, rather, the toxemia and sepsis and peritonitis of advanced appendical disease, which was responsible, directly or indirectly, for the fatal outcome. Death occurred with a fair degree of promptness; 18.3 per cent of all the patients who succumbed died within twenty-four hours and only 28.4 per cent of them were alive at the end of five days. As to mortality in relation to anesthesia, with local anesthesia the death rate was 46.4 per cent; with spinal anesthesia, 17 per cent, and with general anesthesia, 7.9 per cent. Miller concludes: The major factor in the mortality of appendicitis is the mortality of delay, and only by the reduction of the interval between the onset of the symptoms and the institution of surgical relief can that mortality be brought within reasonable limits. A certain percentage of the patients operated on within twelve hours or even within twenty-four hours will inevitably die, for appendicitis is sometimes so virulent from its inception that no mortal hand can stay its course, while some surgical accidents are bound to occur which no amount of care or skill can avert. But the majority, the overwhelming majority of early cases of appendicitis, will go on to recovery, and uncomplicated recovery at that, and what the outcome will be in any given instance rests not in the lap of the gods but on the promptness with which the patient seeks relief and the surgeon offers it. Other considerations cannot be ignored, but no other one really matters.

Royle's Operation of Sympathetic Ramisection.—Poate defends the value of this operation on the basis of twenty personal cases and examination of many of Royle's patients. He says: Spasticity following definite cortical injury gives the best results. The final selection of patients for operation should be left in the hands of those experienced in the operation and its results. The operation should not be undertaken by a surgeon who has not had an opportunity of being instructed by a competent authority. Operation is inadvisable unless facilities for a prolonged course of reeducative after-treatment are conveniently at hand. In borderline cases in which it is difficult to predict any definite improvement, it is as a rule worth while for the patients to undergo operation. Some pleasing surprises have occurred and in any case no harm can result to the individual. Patients whose mentality has been grossly interfered with and who cannot cooperate in the after-treatment are better left alone. The definite presence of excessive tone is usually (but not always) the best indication of a satisfactory result by operation. It is at times noticeable in patients with more than one limb affected that, when one limb has reacted favorably to operation, improvement in the other limb follows to some extent. The question of the economic value of the individual before and after operation is difficult to determine, but in certainly 50 per cent of cases the patients are made more useful members of the community after operation. In many patients, relief from obstinate constipation has been noted. Some of the patients had suffered severely from chilblains and other vascular disturbances which completely cleared after operation.

Virus of Tsutsugamushi Disease and Demonstration by New Method.—By inoculation of the virus into the anterior chamber of the eye of rabbits, Nagayo et al. produced a characteristic eye symptom that can be faithfully transmitted to generations of rabbits by inoculations into the eye chamber of the infected aqueous humor. These eye symptoms they were able to demonstrate through histologic examination, immunologic relations and monkey inoculations to be specific inflamma-

Exanthematous Fever and Weil-Felix Reaction.—In a number of cases of exanthematous fever Plazy reports that only two of the patients showed the characteristic little scab at the point of inoculation. Both of the patients were sailors who owned dogs infested with ticks. The other patients were men on duty where regulations forbade dogs. These patients showed clinical histories and serum reactions comparable to those of the first two patients. Facts tend to show that exanthematous fever may be caused by some carrier other than the dog tick—a carrier that leaves no trace at the inoculation point, which would account for the absence of a scab in patients not on land duty. The Weil-Felix reaction was almost constantly positive in these cases.

Malignant Tuberculous Purulent Pleurisy: Treatment. A. Pissavy.—p. 1060.
*Autoserotherapy in Chronic Rheumatism. P. le Floch.—p. 1061.

Gastro-Enterostomy or Gastropylorectomy for Gastroduodenal Ulcers?—Gastro-enterostomy is often followed by serious complications, and by death, either immediate or remote. In the 174 patients with gastroduodenal ulcer thus treated by Hortolomei from 1920 to 1926, 13.7 per cent died. Since 1926 the author has employed extensive gastropylorectomy. Of the ninety patients who underwent this operation, only 6.6 per cent died. Three of the deaths were due to postoperative pulmonary complications. After the adoption of spinal anesthesia associated with local anesthesia instead of a general anesthesia, there were no more cases with pulmonary complications. Not only was the mortality lower with gastropylorectomy but the good results of the operation were maintained; the patients gained weight, digested their food well and did not need a special diet, and in no case did any patient experience persistent intestinal disorders.

Autoserotherapy in Chronic Rheumatism.—After having employed numerous methods of treatment for chronic rheumatismal diseases, le Floch finds that autoserotherapy can be used effectively when other treatments fail. This is especially true when the etiology of the disorder is not clear. Moreover, it seems to reinforce the action of adjuvant remedies. Cases in which it gives the best results are those with mononucleosis, or at least with absence of polynucleosis; however, this does not at all prevent its being used in other cases. It has the advantage of being easily applied and of being within reach of all physicians.

Cerebral Circulation: Methods of Observation and Comparison of Technics. Riser and R. Sorel.—p. 1073.
*Morphine Glycemia Test in Suprarenal Insufficiency. R. Targowla.—p. 1077.
Exotic Dengue: Four Cases. Aubin.—p. 1078.

Morphine Glycemia Test in Suprarenal Insufficiency: Value.—Targowla states that a negative morphine glycemia test (slight or no hyperglycemia) constitutes a sign of suprarenal insufficiency when there is no important thyroid insufficiency. In various rare cases, however, the absence of the reaction may be due only to neurosympathetic inexcitability. The inversion of the reaction phenomenon (decrease of glycemia) does not seem to depend on a suprarenal factor. As to the exaggeration of morphine hyperglycemia, it cannot be validly applied to the clinical diagnosis of a suprarenal hyperfunctioning in the present state of the problem.

*Dilatation of Right Pupil as Objective Symptom of Chronic Appendicitis. P. J. Buchmann.—p. 1094.

Dilatation of Right Pupil as Symptom of Chronic Appendicitis.—Buchmann shows, through his observations of 3,500 cases of chronic appendicitis, that dilatation of the right pupil is a trustworthy objective symptom. In one series of tests 88 per cent of the cases showed dilatation of the right pupil, 6 per cent dilatation of the left pupil and in 6 per cent there was no perceptible difference between the two pupils. In a second series, 93 per cent showed dilatation of the right pupil, 5 per cent dilatation of the left pupil and in 2 per cent there was no difference between the two. He explains this observation as follows: The dilatation of the right pupil arises from a hypergenesis of the filaments of the sympathetic nervous system in the wall of the appendix, which extends upward through the main branches of the system to the pupil. Since the appendix is the only abdominal organ possessing a well developed system of sympathetic nerves, the irritation is a definite indication of appendicitis. The few cases in which dilatation occurs in the left pupil instead of the right are due to variations in the course *of the trunks of the sympathetic nervous system* below the tenth dorsal segment, which cause dilatation of the opposite pupil. As a further proof of the symptom of anisocoria the dilatation disappears and the pupil becomes normal in from two and a half to seven months after appendectomy is performed.

*Utility of Measuring Venous Pressure in Artificial Pneumothorax. P. G. Bosviel.—p. 1105.
Deafness Due to Tympanosclerosis: Present Treatment. G. de Parrel.—p. 1108.
Nodular Exanthematous Fever. D. Olmer.—p. 1110.

Venous Pressure in Artificial Pneumothorax.—The value of measuring the venous pressure in the course of artificial pneumothorax lies in its disclosure of cardiovascular disturbances. In general the heart withstands unilateral or even bilateral pulmonary collapse remarkably well and in the majority *of cases there is no modification of the arterial or the* venous pressure. Bosviel finds that measurement of the venous pressure reveals an unsuspected cardiac compression more clearly than does the measurement of the arterial pressure, besides furnishing more exact data on the ability of the heart to support pulmonary collapse.

*Treatment of Hay-Fever by Suggestion. B. de Rachewsky.—p. 1124.
Hypocalcemia in Myotonic Dystrophy with Cataract. A. Jung.—p. 1125.

Primary Tuberculous Pericarditis with Effusion in Adults.—Audibert and Olmer give the clinical history of the *subacute fatal form of primary tuberculous* pericarditis with effusion, in an adult, a disease which they believe to be more frequent than is commonly thought. A patient with no apparent previous infection feels his vitality declining, becomes weak, loses his appetite and begins to notice dyspnea both day and night when in repose. After a few weeks the dyspnea increases almost to the point of suffocation and does not yield to cardiac tonics; however, there is little pain and no paroxysmal attacks occur. Fever of 38 C. (100.4 F.) or 39 C. (102.2 F.) is constant. The patient is very weak and shows a whitish pallor of the face and skin with slight puffiness of the tissues. The face is wrinkled and assumes a permanent expression of discomfort and painful resignation. There is some irregularity of the heart action, the liver is enlarged and somewhat painful, and the urinary system is always deficient. There is little coughing or expectoration. The only clinical indication in any way pathognomonic is the fact that the cardiac area is greatly enlarged, which is determined by percussion. This suggests roentgen examination, which gives proof of effusion and necessitates immediate puncture of the pericardium, which gives temporary relief from the dyspnea. The liquid thus withdrawn is always abundant, sometimes slightly greenish, often bloody; rich in albumin and lymphocytes it gives a positive Revalta reaction; it causes tuberculosis in guinea-pigs. The liquid reforms rapidly, necessitating frequent punctures of the pericardium. As the disease evolves, the dyspnea, weakness and fever grow worse and other tuberculous localizations, especially pleurisy, often appear. The entire course of the disease rarely exceeds from six to eight months and is always fatal. The most striking feature revealed by necropsy is the marked involvement of the entire pericardium. It contains a greenish liquid; the internal surface is irregular and covered with false membranes, parts of which are floating in the liquid. Between the visceral and parietal portions is a quantity of fibrin which gives a spongy appearance. There are no adhesions between the two portions. The only macroscopic lesions are a few rare granulations on the parietal portion. The pleura always shows abundant effusion. There are no pulmonary tuberculous lesions. The liver, always enlarged, resembles a cirrhotic liver. Pathogenically the disease is not primary as designated but is the result of an earlier, undetected tuberculous infection, which because of its general extent in the pericardium produces this fatal form. Although the syndrome is similar to that of asystole from primary myocarditis, the latter disease can always be distinguished because in it dyspnea is relieved by rest and diet and the patient is then soothed and regains his appetite. Because of the extent of the infection in the pericardium and the subacute evolution of the disease, the writers feel that no treatment can be more than palliative; at least a cure has as yet not been discovered.

Treatment of Hay-Fever by Suggestion.—De Rachewsky maintains that hay-fever can be cured by suggestion and that the effect of pollen is a delusion analogous to belief in the contagiousness of warts. At first he used small doses of morphine or codeine along with treatment by suggestion in order to relieve inflammation of the mucosa and to lower the nervous tension of the patient, just as common colds may be cured with morphine. For several years, however, he has been using suggestion without the aid of morphine, with equal success. A number of cases are cited, extending over a period of thirty years, in several of which the patient was cured by suggestion alone. The real remedy, he insists, is firm belief in the harmlessness of pollen, armed with which belief one can go into the fields without fear of sneezing. The strong psychic element in the disease is confirmed by analogy with other periodic conditions, as gastro-intestinal disturbances and attacks of depression; also by the fact that hay-fever is never observed in children under 8 years of age.

Vulvar Ulcer with Vincent's Fusospirillary Infection. F. Chatillon.—p. 473.

*Extra-Uterine Pregnancy at Term: Diagnosis and Treatment. J. Hébert.—p. 475.

Test of Labor Before Cesarean Section in Cases of Contracted Pelvis.—Brouha maintains that, in a large proportion of cases of contracted pelvis, cesarean section can be avoided by using the test of labor to give every opportunity for natural delivery before resorting to surgical intervention. Observation was made of a hundred parturients with a conjugata vera ranging from 8 to 9.5 cm. The patients were kept under strict surveillance from the moment of the rupture of the bag of waters; notes were taken every hour, or even every half hour. When the uterus began to contract spasmodically, morphine was administered to relieve the pain and to reestablish the normal rhythm of contraction. In the 94 cases under consideration (6 of the 100 patients mentioned had a conjugata vera of 10 cm.), 61 (or 63 per cent) had a normal delivery and 33 (37 per cent) required cesarean operation. There were no deaths among the mothers. Four infants died; one of the deaths could have been avoided by closer observation. In general, natural delivery was more frequent in cases in which the pelvis was larger and the child weighed less. The chief danger in employing the test of labor is that there are no definite indications to show just when cesarean intervention is necessary to avoid serious complications. The method should therefore be used only in obstetric clinics with a competent personnel. The duration of labor in the 94 cases ranged from seven hours to fifty-eight hours when operation was not performed and from six hours to fifty-one hours when cesarean section was done.

Extra-Uterine Pregnancy at Term: Diagnosis and Treatment.—Hébert gives the history of a case of extra-uterine pregnancy in a woman, aged 36 (no previous illnesses, normal menstruation from the age of 13, first normal pregnancy at the age of 24, several successive normal pregnancies). At her first visit to the hospital in the fifth month of pregnancy the diagnosis was uterine pregnancy with a fibroma at the right. There were two separate growths on the left and right sides, the left one of the consistency of a gravid uterus, the right one firmer. The mass on the left grew steadily larger. The sounds of the fetal heart were heard at the left. In the ninth month the fetal movements ceased. The condition of the patient grew serious and she had a slightly fetid, brownish metrorrhagia and a temperature of 40 C. (104 F.). Manual dilation of the uterus under spinal anesthesia showed a small uterus slightly enlarged; the abdominal pregnancy extended from the upper left portion of the abdominal cavity down into the vesico-uterine culdesac; the mass at the right was also independent of the uterus. A median incision extending from the pubis to above the umbilicus was then made. A gestation sac occupying the entire abdomen was easily exteriorized, revealing first the left part of the tumor the size of a gravid uterus, of violet color, tense, tympanic, free, and surrounded by translucent membranes that allowed the fetus to be observed, and second, the right mass, of a more reddish color, adhering to the rectovesical fascia. The gestation sac was in front of the uterus, which was slightly enlarged. The sac was opened outside the abdomen and a macerated fetus extracted, which was surrounded by an extremely fetid, greenish liquid. The placenta occupied the right part of the tumor and was easily separated. The free part of the sac was removed but not the attached portion where the placenta was inserted. In a few days the patient showed normal temperature, the absorption of the exteriorized mass took place slowly, and within two months after the operation the patient left the hospital cured. In general, the only pathognomonic symptom of extra-uterine pregnancy is the sensation of a small uterus at the side of the ectopic mass. An infallible test, however, may be made by roentgen examination. Sometimes at term a false labor appears with expulsion of the decidua; the fetus dies. If this is determined correctly, a diagnosis of extra-uterine pregnancy can safely be made. After term, any pregnancy prolonged several weeks or months is undoubtedly ectopic. The size of the abdomen is reduced and the fetus begins to dry up and harden. In extra-uterine pregnancy, if the fetus is alive, it is better to wait until term for delivery. If the fetus is dead, operation should be performed about six weeks after the death of the fetus, unless danger of infection necessitates earlier intervention. In operating, a median incision above and below the umbilicus is used. The tumor is exteriorized as well as possible. The placenta is usually left in the abdomen if the fetus is alive, because of the danger of hemorrhage. Marsupialization is often used, with success, especially if the fetus is dead. Most surgeons do not attempt to remove the sac.

*Leukocytes in Blood of Children. M. Erlich.—p. 475.

Antituberculosis Vaccination with B C G. R. Chaussinand.—p. 496.

Leukocytes in Blood of Children.—Erlich examined the blood of about 500 children, ranging in age from 1 day to 14 years, in order to determine the pathologic modifications of the leukocytes in various diseases. Leukocytosis, deviation to the left and toxic changes in the cells were found to be more or less important symptoms in the diagnosis of septicemia, erysipelas, pneumonia, ulcerative stomatitis, suppurative appendicitis (but not chronic or nonsuppurative), tuberculous meningitis, Heine-Medin disease, nontuberculous meningitis, purulent meningitis, typhoid, bacillary dysentery, acute colitis, scarlatina, measles, nontuberculous bronchial pneumonia (as distinguished from the tuberculous form), congenital and visceral syphilis, von Jaksch's anemia, pseudoleukemia, lymphosarcoma, granulomatosis, and severe alimentary intoxication. On the contrary, no modifications of any note were found in tuberculous pleurisy and peritonitis, and various forms of anemia.

Pulmonary Diseases and Tuberculous Infection in 1929. G. Caussade and A. Tardieu.—p. 616.

Phrenicectomy: Mechanism of Action: Results.—In 120 cases of pulmonary tuberculosis with exeresis of the phrenic nerve, 65 showed no improvement either immediate or remote;

within the first few weeks 35 showed rapid and lasting amelioration; in 10 cases there was a belated improvement, while 10 others showed transitory improvement. Dumarest et al. endeavor to explain the discrepancy between the anatomic and clinical results of phrenicectomy as well as the variability in the clinical results. A parallel variability in the mechanism of action of the phrenicectomy must account for the latter phenomenon. The authors find that permanent amelioration depends on the associations of two kinds of factors: on ascension-resistance factors if the improvement is immediate, on immobilization-retractility factors if it is remote. The disappearance of any one of the factors accounts then for transitory amelioration. In all cases the efficacy of phrenicectomy depends to a large degree on the patient—whether he presents a tendency to fibrous tissue formation and whether the lesions have any power of retraction. Left phrenicectomy gives better results than right phrenicectomy.

Arterial Tension in Pulmonary Tuberculosis.—In the opinion of Leuret and Caussimon, hypotension is not an absolute rule in pulmonary tuberculosis. It is not necessarily the accompaniment of serious forms. Inversely, forms of pulmonary tuberculosis of serious prognosis may offer normal or quasi-normal arterial tension. The study of arterial tension scarcely permits a classification of patients according to the degree of activity of their lesions. Sometimes the figures of the tension contradict the clinical record; sometimes the differences between the various measurements are slight compared with the much varied clinical gradations. On the contrary, the systematic study of arterial tension in one patient will permit observation, to a certain extent, of the evolution of the lesions. It must be remembered that in cases of pulmonary tuberculosis the circulatory function maintains its equilibrium over a long period of time in spite of numerous causes of alterations. There exists, therefore, an important period during which the tension remains normal or is slightly lowered without being influenced by clinical nuances then observable. When the lesions become active and in process of evolution, there is a period of reaction during which the tension, the oscillometric index and the maximum-minimum coefficient rise. Then comes a period in which the organism yields to the disease. The index falls, the oscillometric curve tends toward the horizontal, the maximum and the minimum approach, and the systolic coefficient tends toward unity.

Complete Left Subastragalar Dislocation. A. Delahaye.—p. 342.
Simple Method for Correct Construction of Paster Beds. A. D. Radulesco.—p. 346.

Tuberculosis of Calcaneus in Children. — Pouzet discusses twenty-four cases of tuberculous osteitis in young children, a few of whom were less than 6 years of age; the greater number comprised children between 9 and 11 years. The disease was found more frequently in girls than in boys. In some cases there were associated lesions. In twenty cases there were abscesses, twelve of which had previously become fistulous. The patients were treated by a thorough curettage following immobilization in a plaster cast. Complete cicatrization resulted in from four to ten months. Fistulous abscesses were slower in healing than intact ones. Patients treated by complete curettage of the calcaneus recovered as quickly as those treated by partial curettage. The author emphasizes the importance of an early operation and of a complete, thorough curettage. Practically complete conservation of the normal form of the calcaneus and of the subastragalar movements resulted from curettage in the cases of osteitis of the calcaneus in the older group of children.

Syphilitic Osteoperiostitis Mistaken for Schlatter's Disease.—A case, which from the roentgenogram had been interpreted as Schlatter's disease, was in reality syphilitic osteoperiostitis at the level of the head of both tibias. There was a localized gumma with local symptoms of hereditary syphilis. The Bordet-Wassermann reaction was strongly positive. Lupen and Janu administered antisyphilitic treatment and the patient improved notably after the first series of injections.

*Azotemia Without Renal Lesions. M. Roch.—p. 497.
Tuberculous Primary Infection in Children and B C G Vaccine. Jaquerod.—p. 523.

Azotemia Without Renal Lesions.—In a study of azotemia without renal lesions, Roch affirms that a laboratory examination has no more absolute value than the attestation of any clinical symptom. Both must be interpreted and confronted with all available information. He demonstrates that gross errors may follow if an increase in the amount of blood urea is invariably interpreted as a nephritis. A large number of varying causes may bring on azotemia due to insufficient elimination of urea (nervous cause, of reflex origin, suprarenal azotemia, azotemia due to asystole, to oliguria, and to chloride deficiency). Azotemia may also be due to overeating and to an increased production of urea (inanition; traumatic, postoperative, and athreptic azotemia; azotemia due to hemolysis, roentgen therapy, infectious diseases, influenza, pneumonia, typhoid, poisons; hyperhepatia and hepatonephritis). These conditions may be found singly or in association.

Antidiphtheria Vaccination in Geneva. H. Audeoud.—p. 593.
Two Useful Formulas for Iodoform Medication in Tuberculosis. W. Francken.—p. 595.

Use of Urinary Antiseptics.—Jæggy first mentions the futility of urinary antiseptics in infections involving urinary stasis. Because of the metastatic character of many urinary infections the source of the disturbance, whether local or general, should always be considered in the treatment. The actual urinary acidity (p_H) should be ascertained daily by testing with phenolphthalein, neutral red and methyl red. The urinary p_H must be modified in either an acid or an alkaline direction according to the nature of the infection and the antiseptic to be used. Methenamine, for example, acts only in an acid medium. The value of urinary antiseptics, contrary to former opinion, does not correspond to their bactericidal power in vitro, as most of them have an entirely different action in a living organism. Methenamine alone acquires special bactericidal qualities in urine by liberating formaldehyde. Heavy metals, especially silver and gold, in colloidal form and complex salts are more efficacious than ionized metallic salts. *Methenamine, as mentioned, has a direct bactericidal effect* in an acid medium, especially valuable against colon bacilli. Arsphenamine is used in the treatment of syphilis, recurrent fever, malaria, tropical ulcers and other diseases; it is particularly efficacious in staphylococcal infections. Mercurochrome-220 soluble, although more powerful than any other antiseptic, is dangerous and should be used only in exceptional cases in which other remedies have failed.

Cancer of Thymus. M. Baer.—p. 732.
Clinical Studies on Edema. F. Wanner.—p. 736.
Oral Administration of Antistreptococcic Serum. F. Grote.—p. 739.

A Symptom of Heart Disease.—Jarotzky maintains that the circulatory organs, particularly the heart, depend largely on the condition of the entire muscular system. As proof of this he cites the mechanism of the circulation in certain marine mollusks. In these animals it can be observed that during every muscular contraction the blood is forced from one part of the body into another. But even in higher animals the muscular contractions exert a pressure on the veins and thus force the blood toward the center of circulation. The author thinks that a chronic disorder of the myocardium and of the coronary arteries may be caused by various injurious influences, one of them being the reduced action of the muscular system. In these cases the weakening of the muscular system is the primary cause, which is followed by cardiac degeneration; the heart is involved like all the other muscular organs. The author bases this theory on certain observations. In persons whom he had known for a long time he noted a marked change in the physiognomy. The expression of the face changed, the features lost their clear lines and the physiognomy was somewhat masklike. It appeared that the muscles of the face had lost their tonus. These changes in the physiognomy are different from those of an edematous character and also from those in aging persons. The symptom is noted in persons with full mental and physical vigor. It becomes manifest from three to five years before the clinical signs of cardiac degeneration. The significance of the symptom lies in the fact that it indicates the cardiac disorder in its early stage.

Ten Years of Practice in the Tropics. K. E. Surbek.—p. 778.

Pain Caused by Artificially Increased Pressure of Cerebrospinal Fluid.—The symptom described is based on the same principle as Queckenstedt's sign. When the veins in the neck are compressed, the pressure of the cerebrospinal fluid increases rapidly. The author reasoned that the increased pressure would cause pain at the point where a disease process is located. He describes his observations on one patient and he comes to the conclusion that by pressure on the veins of the neck it is possible to produce a pain wherever a pathologic process is located within the spinal canal or in its surroundings. The reaction sets in several minutes after an elastic tourniquet has been applied. The pain increases gradually and subsides again after the tourniquet is removed. Regarding the technic of the test, Pometta states that the tourniquet should be applied to the neck for not less than from five to eight minutes and the pressure should not be too great. He points out that only the positive reaction has diagnostic value. It is probable that not all pathologic symptoms will react to the test. But it might be helpful in such conditions as tabes, sciatica, tumors of the spine, coccygodynia and acroparesthesia. The test is contraindicated in severe hypertension, in case of cerebral processes, in arteriosclerosis and in acute meningitis.

*The Lange Test Applied to Cerebrospinal Fluid in Children with Infantile Paralysis. F. Peola.—p. 767.
Meningitis Due to Bacillus Coli. A. Bardisian —p. 777.

The Lange Test in Children with Infantile Paralysis.—Peola concludes from her researches that the reaction curve of the colloidal gold test on the cerebrospinal fluid in infantile paralysis is, with few exceptions, fairly characteristic, showing usually deviation toward the left—namely, toward the zone of weaker dilution. The flocculation ranges in the first five or six test tubes from 1:10 to 1:160. It is not generally an intense reaction but rather moderate, almost never going beyond the "blue" and only occasionally reaching "clear blue" or "clear pink." The time of securing the fluid, at least in the first and second week, does not appear to have a demonstrable influence on the course of the curve or on the intensity of the reaction. Departing from normal are the cases in which clinically evident signs of intense meningeal reaction were demonstrable. In these cases the curve did not stop with the fifth to sixth test tube but continued to the seventh or eighth. In only one case was the colloidal gold test normal or, better, negative, while the clinical observations and the chemical and cytologic examination of the fluid resulted frankly positive. In the types of tuberculous meningitis, which the author lists in the table for the purpose of comparison, although the cases are too few to form a basis for any definite conclusions, the curves do not seem to demonstrate any point of contact with those of poliomyelitis. In the nonorganic diseases of the nervous system, in which the toxic factor intervenes, the reaction is in general frankly negative or close to normal. The curve of poliomyelitis resembles that of neurosyphilis, but the flocculation reaction is rather less marked in poliomyelitis than in neurosyphilis.

Echinococcus Cysts of Spleen: Treatment.—Capecchi's personal experience, supported by the evidence of recent writers, induces him to conclude that the operation of choice for echinococcus cysts of the spleen is marsupialization, performed in one or two stages, depending on the case.

*Behavior of Calcium and Phosphorus in Persons with Fractures. F. Bellelli.—p. 966.
*Hemorrhagic Steatopancreatic Necrosis of Traumatic Origin. G. Scaglia.—p. 971.

Behavior of Calcium and Phosphorus in Persons with Fractures.—Bellelli found that calcium in about 90 per cent of the cases diminishes, during the first few days after a fracture, by from 2 to 25 mg. per hundred cubic centimeters, from the average figure (10 mg.). The calcium-phosphorus quotient in young persons between the eighth and sixteenth days was 60; it averaged a little above 60 in adults between the seventeenth and twentieth days and rarely reached 60 in elderly persons more than 60 years old, on the thirtieth day after the fracture. These values in the blood of persons with fractures coincides with the period of clinical recovery from the fracture.

Hemorrhagic Steatopancreatic Necrosis of Traumatic Origin: Case.—Scaglia reports that in a man, aged 55, a drinker, a trauma of the abdomen caused a grave and painful syndrome, which brought about his death in a week, from hemorrhagic fatty steatonecrosis of the pancreas and complicating diffuse peritonitis. The case, which came to necropsy, is of interest from the pathogenic angle and from the standpoint of an accident.

*Depressing Effects of Quinidine Sulphate on Contractility of Myocardium. F. Martin.—p. 339.

Depressing Effects of Quinidine Sulphate on Contractility of Myocardium.—Martín presents electrocardiograms and reports the case of a patient, aged 48, with typical complete arrhythmia caused by auricular fibrillation. The electrocardiograms were made at the time of admission of the patient, nine days after admission (while receiving a treatment with quinidine sulphate), and two weeks later (when the arrhythmia had disappeared and the treatment had been stopped). The first electrocardiogram shows complete arrhythmia caused by auricular fibrillation with a frequency of 180 heart beats a minute and a normal T wave. The second electrocardiogram shows a descent of the ventricular rhythm to 100 beats but a reversed T wave. The third electrocardiogram shows a disappearance of the complete arrhythmia and a positive T wave. When the last electrocardiogram was made, the pulse was normal with 80 beats. The treatment with quinidine sulphate in this case reestablished the normal sinusal rhythm. The reversed T wave in the second electrocardiogram, however, indicates the depressing effect of quinidine sulphate on the contractility of the myocardium. This myocardial depression may endanger the patient's life. Hence the necessary careful observation in the changes of the cardiac rhythm of patients subjected to quinidine treatment and the advisability of avoiding quinidine treatment in patients who present a complete arrhythmia associated with symptoms of cardiac insufficiency.

Phrenic Avulsion in Pulmonary Tuberculosis: Results.—Graf states that, in 136 patients with pulmonary tuberculosis, phrenic avulsion was followed by healing in 35, improvement in 77, no change in 21, and an exacerbation of the condition in 3. Before the operation, the sputum of 133 of the patients had contained tubercle bacilli; after the operation it was bacillus-free in 58. Of 67 of the patients (almost exclusively cases with cavern formation) who have been under observation for from two to six years, 83.5 per cent are alive, 62.5 per cent are bacillus-free and 53.5 per cent are able to do their regular work.

Thoracoplasty in Pulmonary Tuberculosis.—On the basis of his experiences in thirty-six thoracoplasties for pulmonary tuberculosis, Sachs states that the complete operation is indicated in the following conditions: (1) in severe, extensive, unilateral, cirrhotic phthisis with cavern formation in which, in spite of marked contraction and depression of the thoracic wall, the caverns have not become obliterated, bacilli are eliminated and the process remains active; (2) in extensive unilateral, cavernous processes in which the caverns are refractory to all other forms of treatment; (3) in moderately severe productive-cirrhotic phthisis with marked distortion of the diaphragm, if a cardiac insufficiency is imminent because of displacement of the mediastinum and if the general condition of the patient grows worse; (4) in unilateral mixed forms if profuse hemorrhages or other accidents that cannot be influenced in any other way threaten the life of the patient; (5) in incomplete pneumothorax which, despite the fact that it has been maintained for a long time, does not cure large caverns because of the presence of extensive adhesions; (6) in a pneumothorax empyema. Partial thoracoplasty is indicated in localized processes in the upper and lower lobes if the total operation is contraindicated on account of the poor general condition of the patient and if the amount of sputum is small; this group of cases includes particularly patients with caverns with rigid walls surrounded by cirrhotic tissue but in whom the rest of the lung is normal because in such cases complete collapse cannot be attained and in plastic operations on the upper lobe there is danger of aspiration pneumonia in the lower lobe. Thoracoplasty is contraindicated in persons more than 45 years of age and in high fever, progressive processes, general cachexia, moderately severe and severe diabetes, cardiac insufficiency with dyspnea, cyanosis or edema, chronic nephritis, amyloid degeneration of the kidneys, renal or intestinal tuberculosis, toxic diarrhea and extensive tuberculosis of the bones.

Artificial Paralysis of Diaphragm in Pulmonary Tuberculosis: Indications.—Sachs summarizes his experiences in 136 phrenic avulsions thus: In pulmonary tuberculosis phrenic avulsion has a place as an independent procedure among the collapsing operations but its effect on bacilli and caverns is much less than the effect of artificial pneumothorax and thoracoplasty. On the other hand, it constitutes a good supplementary operation for increasing the action of other methods of collapse.

Miliary Pulmonary Tuberculosis: Curability.—Sachs reports two cases of miliary pulmonary tuberculosis in which serial roentgenograms showed complete retrogression of the pathologic changes in the lungs and in which the clinical cure of the patients was complete.

Mechanism of Paroxysmal Cardiac Dyspnea and of Bronchial Asthma. Henius.—p. 1360.

Diastolic Blood Pressure Following Bodily Exertion.—In functional tests of the circulation after bodily exertion, Schellong observed that in some persons the diastolic blood pressure showed a marked decrease. He made tests on healthy persons and on persons with vasoneurosis and hypertension. The bodily exertion to which the persons were subjected was the climbing of stairs (fifty steps). Immediately after the exertion the systolic and the diastolic blood pressure was determined by auscultation, and the heart frequency was registered with the electrocardiograph. Diagrams show the results of the tests. The author comes to the conclusion that the determination of the diastolic blood pressure after bodily exertion reveals certain conditions that cannot be detected when only the systolic pressure and the pulse frequency are measured. In the majority of young patients (aged between 15 and 30 years) with vasoneurosis either with or without hypertension, the diastolic pressure shows an abnormally strong decrease. This may be explained by an abnormal dilatation of the peripheral vessels resulting from the bodily exertion and producing in the patient a sensation of palpitation of the heart. The decrease in the diastolic pressure is not dependent on the heart frequency. In other young persons with vasoneurosis there is normal behavior of the diastolic pressure, but a prolonged tachycardia; in only a few of the patients is the reaction after bodily exertion like that in normal persons.

Natural Immunity Reaction of Blood During Anesthesia.—According to Pfalz it is still being disputed whether conduction anesthesia or inhalation anesthesia is the more advantageous method. He made tests to determine the influence of the two anesthetic methods on the bactericidal capacity of the blood. He reasoned that if the shocklike disturbance in the circulation of the patient who has undergone laparotomy is influenced in an opposite manner by the two anesthetic methods, then these opposing influences probably react on the concentration of the immune bodies that circulate in the blood. He determined the bactericidal index in eighteen patients who underwent laparotomy and who had been anesthetized either with chloroform or with ether. It was found that the bactericidal index had increased about twentyfold. Then tests were made on twenty-two patients who underwent laparotomy under the influence of spinal, sacral or local anesthesia. The results were the same as in the patients who had been subjected to inhalation anesthesia. The researches demonstrated that from the point of view of immunology the two anesthetic methods are of equal value.

Value of Determination of Blood Sugar and Diastase.—Bernhard reports that in a case of necrosis of the pancreas the blood sugar content (tested on an empty stomach) was 0.260 per cent. As a result of incorrect conservative treatment the blood sugar increased to 0.370 per cent and following a sugar tolerance test it reached 0.760 per cent. Insulin therapy reduced the blood sugar, which after the operation had been 0.519 per cent, within fourteen hours to 0.266 per cent. The secretion of diastase was not abnormally increased, although almost the entire pancreas was necrotic. In three cases of acute edema of the pancreas with strong secretion of diastase, the blood sugar content was not increased; however, a tolerance test with 50 Gm. of dextrose demonstrated a disturbance in the carbohydrate regulation. It is pointed out that the course of the blood sugar curve indicates the severity of the disturbance. During a relapse that developed following operative treatment of acute edema of the pancreas, a hypoglycemia was demonstrated. The significance of this observation is discussed and the advantages of a sugar tolerance test are demonstrated Sugar tolerance tests indicate the progress in the recovery from acute necrosis and acute edema of the pancreas. The author further discusses the value of diastase determinations for the diagnosis of pancreatic disorders. He shows that by means of diastase and blood sugar tests, with consideration of the clinical aspects, it is sometimes possible to differentiate edema of the pancreas from necrosis. Three cases that were diagnosed in this manner received at first conservative treatment. The author stresses the value of the procedure. It reduces the high mortality in the surgical treatment of acute diseases of the pancreas. During a postoperative parotitis and during a tuberculous parotitis, an increased excretion of diastase in the urine was observed. The influence of the diastase, which is produced in the parotid gland, on the carbohydrate metabolism is demonstrated in blood sugar curves that are made by means of sugar tolerance tests during disordered diastase production and after recovery. In the last part of the article the author discusses the significance of his observations for insulin treatment during acute disturbances of the pancreas.

Significance of Microscopic Examinations of Pathologic Structures for Diagnosis in Gynecology. J. Schiffmann.—p. 1080.
Diagnostic Difficulties in Diseases of Abdominal Organs: Acute Yellow Atrophy of Liver. G. Scherk.—p. 1083.

Disease of Intrapulmonary Lymph Nodes.—Gerhartz directs attention to the fact that in roentgenograms of the lungs there appear frequently small shadows. They are usually circular, clearly outlined and dark but are not close together. In contradistinction to the foci of tuberculous processes, they appear in a systematic order. The author asserts that the shadows have no connection whatever with the primary tuberculous infection or with disseminated tuberculosis. Careful observations convinced him that they indicate an infection of the intrapulmonary lymph nodes. That the disease conditions of the lymph nodes are usually of a tuberculous nature is proved by the fact that the pulmonary adenitis generally concurs with tuberculous processes. However, it concurs also with nontuberculous conditions. It was noted in cases of bronchial asthma and in a soldier who developed empyema following a gunshot injury of the lung. The case of a girl, aged 15, proved that it may also develop in an otherwise healthy person.

Spinal Syndrome in Chronic Myeloid Leukemia.—Hettfleisch states that, although spinal symptoms are extraordinarily frequent in cases of pernicious anemia, they are extremely rare in the various forms of leukemia. In pernicious anemia the nervous symptoms generally involve only the spinal cord and the various neuritic disorders are rare. However, the leukemic nervous disturbances are polymorphous. The author discusses the various forms and finds that in most instances the cerebral nerves are involved and spinal symptoms are an exception. Among the numerous patients with leukemia who received treatment in the clinic in Rostock, the author observed one noteworthy case of which he gives a detailed report: A man, aged 48, had an atypical chronic myeloid leukemia. Enlargement of the spleen was absent and only one axillary lymph node was enlarged, but the blood picture was characteristic of chronic myeloid leukemia. The nervous symptoms involved only the spinal cord, and the cerebral nerves were not affected. What pathologic conditions were the underlying causes could not be definitely established; but the author thinks that the symptoms indicate a leukemic, funicular myelitis. The fact that the nervous disorders could not be influenced by the treatment of the leukemia speaks neither for nor against a leukemic myelitis because it is possible that this form of spinal disorder is refractory to the therapy of the primary disease in the same manner as the funicular myelitis of patients with pernicious anemia is in most instances not influenced even if the blood status of the patients improves.

*Experiences with Irradiated Substances in Treatment of Surgical Conditions. O. Ried.—p. 913.
Progress in Diuresis Therapy. P. Saxl.—p. 916.

Early Treatment of Syphilis by General Practitioner.—In the first part of the article, Kerl stresses that in doubtful cases it is necessary to search for spirochetes. He then discusses blood tests and examination of the cerebrospinal fluid. Further he defines the terms abortive and preventive cures and in what cases each of them is advisable. Treatment with arsphenamine, with bismuth and with mercury is discussed, and also the complications that may develop. In the conclusion he states that early diagnosis and treatment of syphilis is of importance for the patient for the combating of venereal diseases and also for the physician himself, for if a physician should fail to detect a new syphilitic infection the patient will no longer have confidence in him.

Experiences with Irradiated Substances in Surgical Conditions.—Ried points out that if certain substances are irradiated with ultraviolet rays, with roentgen rays or with other kinds of rays they acquire the power to emit rays. Such rays have been demonstrated by means of the photographic plate. However, the fact that they influence biologic objects and may exert a therapeutic action has not received sufficient recognition. The author attempted to use them in the treatment of ulcerations and wounds. He employed irradiated fats, such as an ointment and olive oil, and also metals, namely, aluminum and tin. It was found that when the metal foils were exposed to the direct influence of the quartz lamp they checked the development of human tissues rather than increased it. However, when the metals were exposed to irradiated fats, that is, when the irradiation was indirect, they promoted the growth of tissues. The author assumes that the therapeutic action of the irradiated substances is due to their stimulating effect on the cell metabolism. However, the cells become gradually accustomed to the same stimulation and the substance is no longer effective. In this case a different substance should be used. In the treatment of chronic ulcerations the alternate application of indirectly irradiated aluminum and of directly irradiated tin has proved successful. The author further gives several case reports. In a patient with arteriosclerotic gangrene of the great toe good results were obtained with irradiated ointment and with the alternate application of indirectly irradiated aluminum and with directly irradiated tin. This combination therapy also proved successful in a case of varicose ulcers. The irradiated ointment proved effective also in the treatment of carbuncle, abscesses of sweat glands, phlegmons, erysipeloid, pyodermia and frost bites.

Operating in Sitting Position. W. Sudhoff.—p. 1916.
*Injury of Duodenum from Kick in Abdomen: Case. H. Schmorell.—p. 1919.

Reconstruction of Patella.—Nowosseljzew describes how it is possible to reconstruct the patella in cases in which it was necessary to remove that bone or when it was destroyed by disease. He fashions a patella from the upper anterior aspect of the tibia and, by tunneling, using parts of the lateral ligaments and strips of fascia lata, he constructs a repository for the new patella. The periosteum-covered face of the bone is placed downward; thus the spongy side is "face up." He reports a case in which this operation completely restored every function of the joint, the patient being entirely free from pain or discomfort.

Subcutaneous Injury of Duodenum.—In the case cited by Schmorell, a young man received a severe blow in the upper part of the abdomen from the knee of a fellow player during a baseball game. He suffered immediate severe pain but after a few moments returned to the game. An hour later, severe pain and vomiting forced his retirement from the game. A physician was summoned and he made a diagnosis of intraperitoneal trauma. This was confirmed at operation. On the posterior wall of that part of the duodenum which crosses the spinal column there was a small perforation from which bile exuded. The hole was closed and the patient made an uneventful recovery. There was no external evidence of any injury.

*Arthritis Deformans in Children. J. C. Schippers.—p. 27.
Topographic Peculiarities of Arteries of True Pelvis. C. A. J. Quant.—p. 43.

Arthritis Deformans in Children.—Schippers describes in detail four cases of arthritis deformans he observed in children ranging from 2 to 10 years of age. The onset is usually slow. Some fever of an irregular type, lack of appetite and a bad facies are the first symptoms. After a time, attention is called to one or more joints by the fact that they show some swelling or give evidence of pain and functional disturbances. Often the anomalies are symmetrical. There develop near the joints painful puffy swellings. The capsule is usually thickened and sometimes a bursa is swollen. After a variable period, other joints become involved. It is a peculiar fact that the spinal column is commonly temporarily affected. The movements of the head are thus somewhat limited. During the sickness, periods of high fever occur repeatedly, which show a strongly intermittent character. The anomalies may disappear entirely and the patient is apparently recovered. But after a varying period the symptoms may return. While the functional disturbances may at first be slight, finally the capsule and likewise the surrounding tissues may shrink, and contractures may arise that result in fixed positions and luxations. Skeletal changes do not appear until the last stage. The clinical aspects may then correspond closely to the manifestations of arthritis deformans in adults. It is peculiar that the heart is almost never involved. To be sure, a fibrinous pericarditis or a left-sided fibrinous pleuritis sometimes develops. Muscular atrophy is usually noted early, which causes the swollen joints to stand out even more boldly than otherwise. The blood picture is not characteristic. There is, as a rule, a marked anemia, and, during the fever periods, a mild leukocytosis, often with deviation to the left. Sometimes leukopenia is observed. Blood cultures are always negative. The cause of arthritis deformans in children is unknown. Remedies do not help much. The pain can, however, be combated with salicylic acid preparations. However, sometimes remarkable spontaneous improvements and even apparent recoveries occur.

the lowest value of all; namely, an average of 2.31 conceptions for each married pair.

All of the figures given demonstrate a trend but fall far short of indicating the real degree of infertility. The data that they contain, however, are susceptible of further analysis, the end-result of which may be regarded as indicating a tendency, even though the absolute magnitude of the figures lacks the authority intrinsic in larger groups similarly analyzed. These data are given in table 6.

It will be noted that those who have been married less than three years and have failed to conceive have been deducted from the infertile matings. As was stated previously, the figure taken is an arbitrary one but, in my opinion, represents a fair allowance for this element of uncertainty. It should also be noted that the factor of contraception has been eliminated from the figures as presented for the infertile group. A brief review of the table shows a definite infertility of nearly 30 per cent in the pituitary group, slightly more than 30 per cent in the thyroid, and over 35 per cent in the ovarian group. All of these figures exceed, and exceed significantly, the infertility exhibited by the nonendocrine series (20 per cent), though the latter group shows a lowered fecundity which is substantially twice that of the usually accepted figure based on community surveys. Reynolds and Macomber [4] conclude that from 10 to 12 per cent represents a fair measure of infertility, and that without allowance for the artificial element of contraception which today must be recognized as a very definite factor. Since it has been carefully excluded from the present survey, it seems fair to assume that the data as presented show not only a lowered fertility through the agency of disease, as might well have been anticipated, but that those patients presenting evidence of an endocrine disorder demonstrate an even greater lowering of fecundity, least marked in the pituitary, and most in the ovarian cases.

TABLE 6.—*Analysis of Infertility*

Datum		Pituitary	Thyroid	Ovary	Nonendocrine
Married, number	(a)	290	182	177	406
Conceived, number	(b)	205	128	122	324

Not conceived and married less than 3 yrs.	(d)	23	8	20	23
Infertile:					
1. Nonconception (c — d)	(e)	62	46	35	59
2. Miscarriage	(f)	14	8	19	18
	(g)	3	1	4	5
	(h)	102	63	78	105
	(i)	76	54	54	77
Infertile, per cent (i / a — d — g)	(j)	28.8	31.2	35.3	20.4

SUMMARY AND CONCLUSION

1. A series of sterile marriages has been reported with regard to the coexistence of various diseases. The marriage histories of a group of normal, healthy, pregnant women have served as controls.

2. It appears that endocrine disorders do not result in a decreased number of marriages.

3. The percentage of sterile marriages is highest in those showing ovarian disease, next highest in thyroid, and lowest in pituitary disorders. In the nonendocrine group studied, infertility was definitely less frequent than among those having endocrine disease. Even with the nonendocrine group the incidence of infertility is double that usually regarded as normal for the community.

FUNCTIONAL DISORDERS OF MENSTRUATION

WITH REMARKS ON ORGANOTHERAPY *

EMIL NOVAK, M.D.
BALTIMORE

Abnormalities in the quantity and rhythm of the menstrual flow are, of course, frequently associated with definite anatomic lesions in the pelvis. This is especially true of menstrual excess, which is much more often due to local than to general causes. The opposite is true of deficiency or absence of the flow, although even complete and permanent amenorrhea may be caused by pelvic disease, as, for example, by lesions which destroy all ovarian tissue.

Even when definite lesions are present, there is little doubt that the associated menstrual abnormalities are often to be explained by disturbances of function rather than by any mechanical effect of the lesions themselves. It is hard, in many instances, to draw the line between the rôles played by pathologic anatomy and pathologic physiology, especially in the present incomplete stage of our knowledge.

In a large group of cases of amenorrhea and scanty menstruation (hypomenorrhea), and also in a considerable proportion of cases of menorrhagia (hypermenorrhea), however, there is no demonstrable lesion of the generative organs, so that it is customary to speak of such cases as of the functional type. Certainly, at any rate, the functional factor is manifested in purest form in this group, and can be studied without the necessity of evaluating the influence of an associated anatomic lesion. Besides the quantitative disorders already mentioned, functional derangement of the sex cycle may manifest itself through disturbances of the menstrual tempo, i. e., too frequent or too infrequent menstruation (polymenorrhea or oligomenorrhea).

OVARIAN THERAPY IN LIGHT OF NEWER KNOWLEDGE OF MENSTRUATION

It is unnecessary to urge that study of the abnormalties of the menstrual cycle must be based on a knowledge of the physiology of normal menstruation. This at once faces us as gynecologists with our problem, for our knowledge of the normal cyclic physiology is still far from complete. From time to time new discoveries make us feel that we are beginning to stand on solid ground, but, in every case the new light has only served to give us a glimpse of still unraveled mysteries. For example, with the discovery, at the very end of the preceding century, of the essential rôle of the ovarian hormone or hormones in the production of menstruation, the problem seemed solved. Our immediate predecessors, in their innocence, at once felt able to distinguish conditions of ovarian excess and, especially, of ovarian deficiency. Spurred on by the then fresh triumphs of thyroid therapy, they were quick to apply the same principles to the new problem. If amenorrhea is the result of absent or deficient ovarian secretion, the mere feeding of ovarian substance was the rational procedure for its relief. And thus, on evidence which now seems pathetically flimsy, sprang up the weedy growth of ovarian therapy which we are now trying to clear away, lest it choke the few hardy plants of truth that have raised their heads since then.

* From the Gynecological Department of the Johns Hopkins Medical School

* Read before the Section on Obstetrics, Gynecology and Abdominal Surgery at the Eighty-First Annual Session of the American Medical Association, Detroit, June 27, 1930.

* Owing to lack of space, this article has been abbreviated in THE JOURNAL. The complete article appears in the Transactions of the Section and in the author's reprints.

The whole subject of the physiology of the menstrual cycle is still in a very fluid state, and constant readjustment of our concepts will no doubt be necessary for many years to come. Recently (in the Gilliam Memorial Lecture of 1929), I[1] reviewed certain important recent additions to our knowledge which make it necessary to revamp our ideas of the mechanism of menstruation and to discard certain long cherished beliefs. For example, evidence has been brought forward which must make us at least question seriously the indispensability of ovulation to menstruation. Again, the almost universally accepted opinion that the life of the germ cell itself is the dominating influence in the cycle, and the one that determines its periodicity—the doctrine of the "primacy of the ovum"—must be abandoned altogether, with, unfortunately, no satisfactory substitute as yet to take its place. The bearing of this one point alone on the question of the causation of the disorders of menstrual rhythm is obvious, as will be discussed later.

Of more general interest, perhaps, because of the propensity to treat disease with "extracts" of one sort or another, if given any encouragement whatever, are the recent discoveries as to the number, nature and relation of the ovarian hormones. In spite of the demonstration by Fraenkel,[2] in 1903, of the physiologic importance of the corpus luteum, there had been no wholly satisfactory demonstration of the assumed properties of this secretion until about one year ago. Praiseworthy efforts had been made along this line by Papanicolaou,[3] Hisaw,[4] and others, but it was only the recent work of Corner and Allen[5] that demonstrated conclusively the correctness of the views held by many that the corpus luteum produces a principle just as important in the menstrual cycle as the follicle hormone.

Following the demonstration of the potency of the follicle hormone in producing typical estrous effects in the lower animals, there had occurred the usual enthusiastic surge to apply this fact therapeutically, just as soon as commercial preparations of the product became available. I do not believe that any one will maintain that these hopes have been realized, or, indeed, that thus far any worth while therapeutic results have been achieved. There are a number of reasons for this failure, but one of them is the fact that the follicle activity is responsible for only a fraction of the cyclic physiology.

The demonstration of the corpus luteum principle, while of great importance from a physiologic standpoint, does not by any means supply all the scientific groundwork necessary for intelligent organotherapy. For example, nothing can be more certain than that other endocrine glands, especially the pituitary, thyroid and suprarenal, play an important part in sex physiology. One can well believe that the ovary is only the immediate portal of entry through which the entire endocrine chain, functioning almost as if it were a single though composite organ, empties its influence into the female sex apparatus.

With regard to the anterior pituitary lobe, the mechanism of this relation has been brilliantly illuminated by the studies of Smith and Engle,[6] and Evans and Long[7] in this country, and of Zondek and Aschheim[8] in Germany. The extremely powerful effects produced on the ovary, and through it on the generative canal, by repeated implantations of anterior pituitary tissue, demonstrate beyond question the importance of the latter in the physiology of the cycle, and—the point with which we are concerned in the present discussion—with its probable importance in many menstrual disorders that in the past were looked on as purely pelvic problems, so to speak. As a basis for later discussion, it is important to remember that the hypophyseal hormone has no direct effect on the genital mucosa, but exerts its effect on the ovaries, so that it has been designated as the "motor of the ovaries." In this lies the chief difference as compared with the follicle substance, which produces a direct estrous effect on the genital mucous membranes, even in animals which have been previously castrated. For a fuller discussion of these physiologic problems I would refer to my previous paper.[1]

There is still much to learn as to the part played in menstruation and its disorders by such organs as the thyroid and suprarenal. Riddle,[9] with much justification, states that "nearly all of the internal secretions are intimately concerned in one or other special aspect of reproduction." He has demonstrated definite seasonal variations in the size of a number of the ductless glands, apparently related to periods of active or inactive reproduction. He believes that the essential processes of reproduction are not under the control of the nervous system. This, however, is not equivalent to saying that the cycle cannot be affected through the nervous system. In the human being, for example, there is ample evidence that nervous and psychic factors may occasionally be important in the production of disorders of menstruation.

Even our present incomplete knowledge indicates a far greater intricacy of the cyclic mechanism than had been anticipated. The reproductive function, because of its essential importance in the perpetuation of the species, seems to be physiologically more deeply rooted than almost any other. This very intricacy of mechanism makes the interpretation of menstrual disorders correspondingly difficult. My discussion of these disorders, therefore, will be disappointingly lacking in sharpness and definition, because of the poor light afforded by our present knowledge. It will deal with broad principles rather than with rules of thumb.

FUNCTIONAL AMENORRHEA AND HYPOMENORRHEA

Functional amenorrhea and functional hypomenorrhea may be discussed together because, so far as is known, the underlying causes are the same. They constitute the largest and most important type of amenorrhea and hypomenorrhea, for local causes, other than the physiologic ones, are relatively uncommon and usually not difficult to recognize. The causes of functional amenorrhea may be grouped into the constitutional and the endocrinopathic, although it is not always easy to draw the line between them.

Constitutional.—It has long been known that constitutional diseases of various sorts, associated as they are with deterioration of the general health, are often characterized by deficiency or absence of menstruation. The latter, therefore, are frequently symptoms of tuberculosis, chronic nephritis, diabetes, and similar debilitating diseases. Amenorrhea is not infrequently found in even incipient tuberculosis, and it may, indeed, be the first symptom noted by the patient.

The various forms of anemia are even more important in this regard. None of the older textbooks failed to elaborate on the frequency and importance of chlorosis in this regard, though now it appears to be a vanishing disease. The explanation of amenorrhea produced by these debilitating diseases has in the past been that it represents an effort on the part of nature to conserve the strength of the patient. Nothing, however, could be said of the mechanism. The experimental studies of McCollum[10] and others, however, have demonstrated that the ovary is singularly sensitive to nutritional influences. This is most clearly seen in the effects produced by deficiencies in the vitamin content of the diet, for dietary defects of this type quickly produce in animals a disappearance of the sex cycle. That the same effect is produced in the human female was illustrated on a grand scale in the "Kriegsamenorrhöe" so widely prevalent throughout the belligerent countries during the privation days of the World War. The immediate ovarian effect produced by this cause is probably an interference with the maturation of the follicles, and, of course, with ovulation.

The present-day prevalence of self-dieting, often extreme, among women makes this cause of amenorrhea of anything but academic interest. While the diet of the average American woman contains a sufficient proportion of the essential vitamins, exceptions are at times found, and are common in the case of women making strenuous efforts to reduce.

Little need be said as to the treatment of amenorrhea due to the causes enumerated here, for it is obviously to be directed to the cause of the disorder. For example, the rational procedure in cases of tuberculosis or anemia is the treatment of these conditions, just as, in the management of amenorrhea due to dietary errors, insistence on a properly balanced diet will effect a cure. Perhaps the most important injunction is to abstain from any direct treatment of the menstrual disorder, whether by the old-fashioned emmenagogue drugs or by the more modern organ extracts. Such measures are irrational, often harmful, and almost always unsuccessful.

Endocrinopathic Amenorrhea and Hypomenorrhea.—This is perhaps the most frequent and most interesting of all types. Its mechanism is varied, and on this variation are based certain clinical syndromes presented by the patients, placing them under different categories. For example, it is customary to speak of a *hypogonadal* and a *hypopituitary* type, while *thyroid* hyperfunction, and, less commonly, thyroid hypofunction, may likewise be of causal importance. It should be recognized, however, that these terms are not based on any exact knowledge of the nature of the relationship implied.

In the so-called hypogonadal type, the endocrine effect is believed to involve chiefly and perhaps only the ovary. The prototype of this variety is the normal amenorrhea after the menopause, or, though not so physiologic, that seen after complete removal of ovarian tissue. One would expect, therefore, to find the subjective and objective conditions similar to those seen after the menopause, but there are numerous exceptions to this. From a subjective standpoint it is true that vasomotor symptoms may be noted, though they are rarely troublesome. There may be moderate or at times marked adiposity, with the heaviest deposits about the abdomen and hips. In other cases, however, where no other endocrine factor than the ovary can be demonstrated, and where other constitutional factors likewise are lacking, there may be no gain, and perhaps even some loss of weight. In short, the tendency has been to apply the designation of "hypogonadal" to cases in which these other factors cannot be established. The precariousness of such a deduction is obvious.

The endocrinopathic cause of amenorrhea for which the most satisfactory scientific evidence is available is that due to anterior pituitary deficiency. This type of amenorrhea is associated with adiposity, sometimes moderate, at other times quite marked. In one of my patients, there had been a gain of 90 pounds (41 Kg.) in one year. The deposit of adipose tissue shows a rather characteristic distribution, with often large shoulder pads, rather large bust, a narrow waist, and heavy deposits about the abdomen, buttocks and hips. The hands are small and delicate, and the fingers slender and rather pointed. There may be little in the way of subjective symptoms, though headache ("pituitary headache") is sometimes complained of. This clinical picture has been rather firmly established in the literature as adiposogenital dystrophy, or Fröhlich's syndrome. It was originally described by Fröhlich[11] in association with a pituitary tumor but is now accepted as occurring with purely functional pituitary deficiency.

There is a sound experimental basis for this view in the studies of Cushing and his co-workers,[12] who demonstrated that partial ablation of the anterior pituitary in female dogs is followed by obesity, together with hypoplasia of the generative organs, manifested clinically by a disappearance of the sex cycle. There has been much discussion as to whether all these symptoms are really of pituitary origin, but the recent studies of Smith[13] appear to leave no doubt that the adiposity is due to associated disturbance of the adjoining hypothalamus, while the changes in the genital tract are unquestionably of anterior pituitary origin. The fact remains, however, that there is a characteristic clinical association between the two sets of changes, so that the resulting syndrome is still commonly designated as adiposogenital dystrophy.

Functional disturbance of the thyroid may likewise be characteristized by amenorrhea or hypomenorrhea as one of the symptoms. This is more frequently the case with hyperfunction than with hypofunction, which, in my experience, is more commonly characterized by menstrual excess. There are, however, numerous exceptions to both these statements, thus confusing the exact nature of the thyroid influence on the menstruation. As with amenorrhea of the hypopituitary type, there is commonly a tendency to obesity if the thyroid function is deficient. The adipose tissue, however, is more evenly distributed, with little tendency to the localizations described in connection with the pituitary variety, and it may show some degree of the infiltrative myxedematous thickening seen so often with hypothyroidism.

If, as is perhaps more often the case, the amenorrhea is associated with hyperthyroidism, the well known characteristics of the latter condition are seen to greater or less degree. I need not stress the importance of studies of basal metabolism in the proper evaluation of these cases, or in their proper management. For that matter, they can rarely be dispensed with in the proper interpretation of any endocrinopathic menstrual disorder.

Associated Symptomatology of Endocrinopathic Amenorrhea.—In a large proportion of cases, there has been, in my experience, little or nothing in the way of subjective symptoms. At times, especially in the hypogonadal cases, there has been a complaint of vasomotor flushes, but these have only occasionally been very troublesome. The same thing may be said of the vertigo occasionally observed. Headache is not infrequent in cases of the adiposogenital dystrophy group.

Nervousness and depression are rather common, but I believe they are due in large measure to the psychic effect produced by the absence of menstruation. This, in turn, is often due to the wrong ideas held by many of the laity as to the significance of menstruation. The belief is still prevalent among the laity that the purpose of the menstrual flow is the purgation of the woman's system of impurities, and that abolition of the function causes a retention of these harmful substances. Again, a superstition often encountered, especially among the less intelligent, is that amenorrhea may lead to consumption, that the girl who does not menstruate is likely to "go into decline." This belief no doubt has its origin in the fact that in many cases of actual tuberculosis amenorrhea is an associated symptom.

In the case of married women who are anxious for pregnancy, the sterility which so often accompanies long standing amenorrhea introduces another factor of the greatest importance in producing nervous and psychic symptoms. *In general there is no doubt that amenorrhea greatly lessens the woman's chances for pregnancy,* although exceptions are not infrequently observed. I have seen pregnancy supervene in a number of cases in which the women had not menstruated for several years. Taken as a whole, it is this group of cases of amenorrhea, i. e., those in which sterility is the underlying complaint, that most often calls for efforts at correction. Among women in whom the picture of the amenorrhea is not confused and overshadowed by the desire for children, it is in a large proportion characterized by few or no symptoms, and the patient may be in as good health as if she menstruated regularly. This statement does not, of course, apply to the far less frequent cases in which some organic lesion, such as a pituitary tumor, is present.

Diagnosis.—From what has been said, it is evident that amenorrhea is merely a symptom of some underlying condition, and not an entity in itself, to be treated by this or that form of organic extract. Every effort must be made to classify the individual case on the basis of careful history and physical examination, with such aids as the laboratory can offer. The latter will often mean such measures as roentgenologic study of the sella turcica, urinalysis, tests of sugar tolerance and studies of basal metabolism. The more obvious types due to such definite diseases as tuberculosis and anemia are determinable by the usual diagnostic methods. The history should be complete enough to bring out such factors as dietary defects, changes in weight, and endocrinopathic manifestations such as marked fluctuations of weight. The physical examination will, of course, include such details, important in endocrinopathic study, as the presence or absence of obesity, the distribution of the adipose tissue, the distribution of hair, the height of the patient, and the condition of the pelvic organs.

Treatment.—There are a good many cases in which endocrinopathic amenorrhea needs no treatment, others in which the treatment need be only a reassurance as to the essential harmlessness of the condition in itself, and still others in which efforts at correction are definitely indicated. To the first group belong the cases of moderate severity, with no subjective symptoms, in which pregnancy is not an important consideration. For example, a woman aged perhaps 35 to 37, whether married or unmarried, will usually choose to forego any treatment if convinced of the harmlessness of the disorder and the usual unsatisfactoriness of the treatment. She will be quite willing to resign herself to a premature menopause, which is about what the condition represents.

In women who have been much perturbed and depressed by the amenorrhea, and especially when this upset is due to such erroneous ideas as I have mentioned previously, the physician can perform a real service by explaining in simple language the real significance of menstruation, stressing the fact that complete absence of the periods is compatible with good health. In a considerable number, however, it is advisable to resort to treatment, with a frank explanation to the patient as to its limitations.

The third group presents the clearest indication for treatment. It includes those cases in which there are definite associated symptoms, and, more particularly, when an associated sterility, otherwise unexplainable, constitutes the problem of immediate concern to the patient. Aside from measures of general hygiene and procedures directed to the improvement of general health, organotherapy of one form or another is the first thought of most practitioners in the treatment of most cases of this group. If based on rational indications, this is, of course, fully justified; but it should be remembered that the organotherapy of endocrinopathic amenorrhea is rather unsatisfactory and with great frequency unsuccessful. I have elsewhere fully reviewed the entire subject of ovarian therapy.[14] Regardless of the possible value of the oral administration of certain ovarian preparations for the subjective symptoms of menstrual deficiency, though even this is open to some question, a review of the literature and a rather large personal experience have convinced me that they have no value in the reestablishment of menstruation in cases of amenorrhea. It is of interest to note that the Council on Pharmacy and Chemistry, after an impartial review of the question, has just decreed the omission of all such preparations from New and Nonofficial Remedies. The same pessimistic statement may be made of the various preparations introduced for hypodermic administration, up to the discovery of the potency of follicle hormone in producing the sex cycle in laboratory animals that had been previously castrated.

As I stated earlier in this paper, the results of follicle hormone therapy in amenorrhea have thus far been extremely disappointing. Its chief value, thus far, has been in the diagnostic field, in the hands of the small group of investigators who have utilized it in this way. Studies of the follicle hormone content of the blood have apparently been of help in differentiating conditions of excess and deficiency, although even this aspect of the work has scarcely passed out of the experimental phase. The problem is further confused by the fact

---

14. Novak, Emil: The Present Status of Ovarian Therapy, J. A. M. A. **91:** 607 (Sept. 1) 1928.

that even amenorrhea may be associated with an excess rather than a deficiency of follicle hormone in the blood (polyhormonal amenorrhea), as shown by Zondek[15] and others. A number of reports have been made as to the production of menstruation by injections of follicle hormone, but they are few and unimpressive. Even when uterine bleeding is produced, it is almost certainly not a genuine menstruation, for the follicle hormone cannot itself complete the menstrual cycle. It probably can bring about a certain degree of hyperemia and hypertrophy of the endometrium, even in human females, if given in sufficiently large dosage, and this may at times be followed by bleeding. But this is not menstruation, for among other things, the ovary plays no part in it, and the endometrial changes are quite different.

The effect of the follicle hormone is exerted on the genital mucosa alone, so that it is to be looked on as purely substitutional and transient. There is no tendency toward a reestablishment of the ovarian cycle, so that it would be necessary to repeat the injections whenever the patient wished to menstruate. There are few patients so anxious to menstruate that they would be willing to continue indefinitely with such treatment, especially when it involves many disagreeable hypodermic injections for every course of treatment. Furthermore, there is not the slightest reason to expect that it would enhance the patient's chances for pregnancy. This question of follicle hormone therapy is fully discussed in a previous paper.[16]

Since the writing of that paper, two other methods of administering ovarian follicle substance have been suggested to obviate the necessity of repeated hypodermic injections. One is the method of administration by vaginal suppository, with which I have had only a limited experience. The other plan, recently suggested by Pratt and Smeltzer,[17] is that of the nasal spray, as the hormone apparently enters the circulation of the patient when given in this way. Neither method can hope, however, to bring about any more potent results than the method of direct hypodermic injection. Since the latter itself is admittedly unsatisfactory in its results, there is little reason to expect any wide adoption of these newer methods, in spite of their lessening of the patient's discomfort.

Within the past few months, Doisy, Veler and Thayer[18] in this country, and Butenandt[19] in Germany, have announced the isolation of this hormone in crystallized form. These crystals are of enormous potency, Doisy and his co-workers stating that each grain of their substance possesses the potency of two million rat units. A substance as powerful as this may some day prove to be of great value therapeutically, but the foregoing pessimistic remarks are based on conditions as they now are, and I believe that they are justified.

In previous papers I have emphasized the fact that the endometrial preparation for menstruation is really a preparation for a possible pregnancy, and that the corpus luteum is just as important in the cycle as is the follicle. If, therefore, an active corpus luteum principle could be isolated, there would be reason to believe that the normal sequence of events in human menstruation could be mimicked much more completely than with follicle hormone alone.

An active corpus luteum extract has recently been prepared by Corner and Allen,[5] although it is not yet available commercially. It will be interesting to see whether the sequence of injections of follicle hormone, followed by injections of corpus luteum hormone, according to the plan which I suggested in 1922, will bring about menstruation more often than injections of follicle hormone alone. This principle, which I have repeatedly urged on the basis of what has been known as to the histologic interrelationships of menstruation, has been firmly established by the work of Willard Allen[20] and of Hisaw.[21] Both of these investigators have demonstrated that the corpus luteum hormone can bring about the characteristic pregravid changes in the endometrium only when the latter has been adequately prepared for this by injections of the follicle hormone. Even the combined plan of treatment, however, would be a substitutional rather than a permanently stimulating treatment, so here again it will probably not have a wide appeal in the treatment of amenorrhea.

Far more promising appears to be the field opened up by recent work demonstrating the effect on the ovary of the anterior pituitary hormone. The method of implantation, used for experimental work, would not be practicable clinically, but already efforts at obtaining the active principle in a form suitable for clinical use are being made.

The oral administration of pituitary substance, on the basis of laboratory studies, is probably worthless, although I am well aware that it is employed by many excellent clinicians, especially in the treatment of adiposogenital dystrophy. My own impression has been, however, that any benefit which commercial preparations of anterior pituitary substance have seemed to confer has come from the thyroid extract which has almost always been combined with them. Within the past few months Collip[22] has published studies which indicate that the oral administration of properly prepared extracts are potent in doses only two or three times as great as those required for hypodermic administration. These results contradict those of Smith and Engle, and other investigators, so that the status of the question is still unsettled. In a very small group of cases of ovarian hypofunction which Campbell and Collip[23] treated by the oral administration of their extract, encouraging results were obtained, but these observations obviously call for multiplication and confirmation. Zondek,[24] Biedl,[25] Seitz[26] and others have likewise been experimenting with anterior pituitary therapy, though by the hypodermic route. Little has as yet been achieved, and the method is said not to be devoid of risk. In spite of its great promise, therefore, this plan of therapy is as yet undeveloped and, of course, inaccessible to most clinicians.

As a matter of fact, thyroid extract still remains the sheet anchor in the treatment of functional amenorrhea, as in so many other endocrinopathies. Its rationale is not always clear, except, of course, when a definite hypothyroidism is present. Even in the absence of the latter, however, the thyroid substance is commonly employed on empiric or semiempiric grounds. It will usually reduce the weight and may cause some subjective improvement, but it will only occasionally restore menstruation, except in the cases of outspoken hypothyroidism.

All in all, therefore, the endocrine treatment of amenorrhea must still be viewed pessimistically, in spite of the glowing promises of successful results pictured in the literature of many manufacturers of organ extracts. Of other methods of treatment, such as radiotherapy of the ovaries and pituitary body, I can say little from personal experience. They have been employed by a number of gynecologists, but the methods do not seem to have achieved any great vogue, which does not argue for any brilliance of result. Rubin,[27] Rongy,[28] and others have reported good results from light roentgenization of the ovaries, but I agree with Frank that the method should be used with great caution, for fear of destroying the follicle apparatus in an already deficient ovary.

FUNCTIONAL MENORRHAGIA (HYPERMENORRHEA)

The subject of functional menorrhagia I shall discuss in only a summarizing fashion, as I have elaborated on it in a number of previous papers.[34] It is seen only during the reproductive epoch and occurs most characteristically at or near the menopause and, less frequently, at or shortly after puberty. It may, however, occur at any period of menstrual life. As a rule the pelvic organs show no demonstrable lesion. The characteristic ovarian finding is an absence of corpora lutea and the presence of a persistent graafian follicle. The endometrium usually shows a characteristic picture, designated as hyperplasia of the endometrium. This, however, is merely the result of the ovarian disturbance, which evidently consists in a persistence of the follicle effect, with no secretory or desquamative changes in the endometrium.

It has been generally believed that the immediate ovarian disturbance associated with functional bleeding consists of an excess or persistence of the follicle stimulus, while the corpus luteum activity is in abeyance. Recent studies,[24] however, indicate that in some cases of amenorrhea a similar excess of the follicle principle is found in the blood, and that the endometrium may in such cases even exhibit a definite hyperplasia. I have myself seen typical hyperplasia of the endometrium in an amenorrheic woman, so that this endometrial lesion cannot be considered to be as constantly associated with abnormal bleeding as has been heretofore believed.

The type of menorrhagia under discussion, however, is certainly of functional origin. Whether the disturbance is really primarily in the ovary or whether it originates elsewhere in the endocrine chain, it is difficult to say. Certainly there are cases of menorrhagia of thyroid origin, as already mentioned, but these are far less frequent than the type under discussion, which can be considered one of the common menstrual disorders.

For the treatment of this disorder, as well as for a full discussion of its clinical and pathologic characteristics, I would refer to my previous papers on the subject.[34] Two new aspects of the problem, however, may be indicated.

The first is the possibility that the anterior pituitary may play an important part in the causation of this disorder. This is suggested by the demonstrated potency of this gland in stimulating follicle maturation, and, under certain conditions, of preventing ovulation by imprisonment of the ova within the follicles. Varying effects are produced by varying proportions of the two hormones which, according to the work of Evans and Simpson,[32] are produced by the gland, and it is quite possible that some disturbance of the normal balance between these two principles is the underlying cause of this type of hemorrhage, especially in view of the ovarian picture that characterizes it.

The second recent development is the successful elaboration, by Corner and Allen,[5] of a really potent corpus luteum extract. Whatever the underlying cause of functional hemorrhage may be, a characteristic ovarian finding is an absence of corpora lutea. The administration of an active corpus luteum extract would therefore be a rational procedure. Thus far no such extract has been available, but, if the work of Corner and Allen results in making such an extract available for clinical use, there is reason to hope that the organotherapy of functional hemorrhage of this type will be more successful than at present. There is, of course, no certainty of this, for there are still many unknown links in the menstrual chain. The use of such an extract, however, should certainly be tried, for this type of bleeding, especially when it affects women in whom preservation of the reproductive capacity is important, constitutes one of the most difficult present-day problems in gynecology.

The employment of hypodermic treatment for this type of pathologic hemorrhage does not possess the disadvantages mentioned in discussing hypodermic medication in cases of amenorrhea, especially as the former is a seriously debilitating disorder. The alternative of organotherapy is usually surgical operation or radiotherapy, both undesirable in younger women. If, therefore, an extract is made available which controls this type of bleeding, it will confer an inestimable boon to patients suffering with this troublesome disorder.

SUMMARY

Recent advances in knowledge of the physiology of menstruation make it necessary to revise the interpretation of the mechanism involved in functional menstrual disorders, and, of course, have a bearing on problems of treatment as well.

Amenorrhea and hypomenorrhea (scanty menstruation) are most often of constitutional or endocrinopathic origin, local pelvic causes being much less common. The ovarian function is singularly sensitive to nutritional and circulatory deficiencies, disappearance of the cycle being the common result. The treatment of the amenorrhea produced by such general diseases as tuberculosis, anemia and dietary deficiencies is, of course, the treatment of the underlying conditions, and endocrine therapy is contraindicated.

Of the endocrine causes of amenorrhea the most common are ovarian deficiency, hypopituitarism and thyroid disorder, most often hyperfunction, but at times hypofunction. These types are often distinguished by fairly well defined clinical syndromes, such as the adiposogenital dystrophy of hypopituitarism, but the scientific basis for such differentiation is often incomplete.

Amenorrhea is often unaccompanied by other symptoms and may need no treatment except reassurance of the patient as to the essential harmlessness of the condition. In other cases, as when it is subordinated to the accompanying sterility, efforts at treatment are indicated, though unsuccessful in a large proportion of cases.

The three organ extracts that are commonly employed are those derived from the ovary, the anterior pituitary and the thyroid, in various combinations. The oral administration of ovarian extracts is worthless, as far as any effect in the reestablishment of menstruation is concerned. The same statement probably applies to the older forms of preparations for hypodermic administration. Ovarian follicle hormone, more recently employed, has so far yielded no worth-while therapeutic results, important as it is physiologically. The recent discovery of an active corpus luteum principle may improve the results somewhat, but these will still be far from ideal, as neither of the principles named apparently has any stimulating effect on the ovary itself.

The treatment of amenorrhea by means of the anterior pituitary suggests itself as offering the best hope for the future, because of the striking effect on the follicle apparatus produced by the hormone of this gland. If the latter is made available for clinical use in some convenient form, its employment in certain cases of amenorrhea and sterility will be rational, although perhaps even with this the results may be disappointing. The oral administration of pituitary substances is probably without value. For the present, thyroid therapy, at times on rational indications, at times on empiric or semiempiric grounds, is still the most popular and perhaps the most frequently helpful plan in most cases.

Not much can be added as to the treatment of too frequent or too infrequent menstruation (polymenorrhea or oligomenorrhea) because of ignorance as to the nature of the factor or factors that normally regulate the menstrual rhythm. The treatment of oligomenorrhea is in general similar to that of amenorrhea and hypomenorrhea.

Excessive menstruation of functional nature (hypermenorrhea) is an extremely frequent and important disorder, especially in women at or near the menopausal age, because of the fact that, like other types of bleeding at this age, it calls for differentiation from that produced by cancer. For a discussion of this disorder the reader is referred to several previous papers. When potent corpus luteum extracts, such as that demonstrated recently by Corner and Allen, become available commercially, their employment in this condition will be rational and may possibly yield excellent results.

Some such system of nomenclature of menstrual disorder as that employed in this paper would seem worthy of general adoption. This would simplify records and indexes materially, through the elimination of such clumsy and circumlocutory terms as "too frequent menstruation," "deficient amount of menstruation," and the like. Various systems of naming these disorders have been suggested, but the one that seems most logical is as follows: amenorrhea, for the absence of menstruation; hypomenorrhea, for a deficient amount of the menstrual discharge; hypermenorrhea, for an excessive menstrual flow; oligomenorrhea, for too infrequent menstruation; polymenorrhea, for too frequent menstruation; dysmenorrhea, for painful menstruation. Various combinations of these terms are at times called for, and would be self-explanatory; viz., oligohypomenorrhea, oligohypermenorrhea, polyhypermenorrhea, and so on.

While the organotherapy of menstrual disorders is still unsatisfactory, the recent additions to our knowledge of the physiology of the sex cycle justify the hope that before long the problem can be approached much more intelligently and precisely than in the past. It would seem quite likely, for example, that the etiology of the various disorders will soon be determinable by studies on the biologic chemistry of the blood. In other words, just as quantitative determinations of blood sugar or blood urea can now be made, it will perhaps be possible to determine deficiency or excess of such principles as the ovarian follicle hormone, the anterior pituitary or thyroid secretions. These methods of course have already been used to some extent, but their refinement, simplification and wider utilization may make of organotherapy a more scientific procedure than it has been in the past.

26 East Preston Street.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. ROWE AND NOVAK

Dr. J. P. Pratt, Detroit: The problem is indeed complex, for the human sexual cycle is so different from the estrous cycle of animals that it is hazardous to draw conclusions from animal experimentation until there has been a complete check in the human subject. The suggestion to adopt a standard terminology is timely. Confusion in the literature would be avoided. Function of the ovary, like other endocrine glands, is either normal, hypo or hyper. Reference to the function of the glands with internal secretion as a "chain of glands" or as being interrelated seems confusing. Would it not be better to think of each tissue or gland as composed of cells which have the ability to take out of the circulation and to utilize materials in a manner characteristic of the tissue or cell? The thyroid, for example, puts into the circulation a hormone which is a definite chemical substance. This is carried to all parts of the body by the blood. Each tissue or organ may utilize this hormone according to the ability of the individual cells to respond to it. The same is true of the other elements of the blood, such as iron or calcium. Thus in the case of the ovary and uterus, if the blood circulating through them does not contain a sufficient quantity of iron or calcium, or hormone of any of the various glands of internal secretion, the activity of the ovary or uterus will be affected accordingly. Since the hormones isolated from the various glands of internal secretion are definite chemical compounds, disturbances of function of these glands are either hypofunction or hyperfunction. In line with this interpretation it would seem that disturbances of function of the ovaries and uterus are due to too much or too little of some material in the circulating blood. However, not all instances of disturbed function are due to a deficiency of the same material; therefore the intelligent treatment of disturbance of menstruation would necessitate determining the lack or oversupply of the material responsible for the abnormality in each individual case. Until such methods of analysis of the blood are discovered, treatment will have to be continued empirically. As suggested, one of the best therapeutic agents for ovarian deficiency is thyroid. This apparently acts on the ovaries directly. I cannot share Dr. Novak's pessimism in reference to treatment of ovarian deficiency by the use of ovarian follicular hormone, for I have followed a small group of cases for a few years in which the combination of thyroid and ovarian follicular hormone has relieved oligomenorrhea and hypomenorrhea.

Dr. Carey Culbertson, Chicago: I take it that the menstrual irregularities which are of the greatest interest are those occurring in young women. Physicians are not so much concerned with the menstrual disturbances of the *older* woman who is approaching the climacteric, because an amenorrhea is expected at that time, and the treatment for excessive bleeding in those years is well known. It is in the young women who suffer from amenorrhea, irregular menstruation and excessive bleeding, whatever name is given it—I myself like the terms which Dr Novak has suggested, and have used them—also in the young women who suffer from dysmenorrhea, that the interesting problems are presented at this time, chiefly because dysfunction is not understood. I am curiously impressed in hearing Dr. Novak's paper by the fact that he makes no reference to the suprarenal glands. When I first began to study the endocrines twenty years ago, I had an idea, based on the work done then by Hoskins and others, that the suprarenals had a great deal to do with ovarian function. Today it is the anterior pituitary and the thyroid influence that is chiefly discussed, but more regarding the suprarenals may yet be heard. The ovary still seems to be, as I have thought of it for some years, an organ that requires stimulation in order to keep it functioning. But this evidently is true of the others as well. Where the stimulation comes from is the interesting thing, and how it is applied. Until that is known, ovarian dysfunction cannot be treated satisfactorily. Just as in studying the climacteric, so in studying these functional disorders of younger women one cannot get away from either the pituitary or the thyroid gland. That is the reason recourse has had to be made frequently, as Dr. Novak mentioned, to basal metabolic and to blood pressure studies. In this connection, I should like to emphasize that one blood pressure reading, one basal metabolic rate estimation is not enough. One has to make repeated estimations of metabolism and of vascular tension in order to understand best the condition to be treated. Theoretically, since the anterior lobe of the pituitary gland seems to be most influential in ovarian function, hypophyseal preparations should be of definite therapeutic aid, particularly in the amenorrheas. Such preparations as are offered, however, have been disappointing. An occasional case may appear to be benefited, but the majority are not.

Dr. Emil Novak, Baltimore: I am afraid that the trend of my paper has seemed much more destructive than constructive. I wish it could be otherwise and that I could suggest some simple and more or less infallible way of curing these functional disorders, but the limitations of this field must be, and should be, admitted. If there is to be advance, the weeds and underbrush must first be cleared away. Dr. Pratt believes he has had good results with the ovarian follicle hormone in some cases of disturbance of menstrual rhythm, although he said nothing as to its use in amenorrhea, which has been supposedly its chief field. As I stated in my paper, we know little as to the cause of menstrual irregularity. When it is moderate in degree, as when a woman menstruates every three weeks or every six weeks, it appears to make little difference to the patient. Thyroid extract is still perhaps the most frequently useful therapeutic agent in cases of amenorrhea, especially when obesity is associated with it. I have elaborated on this in my paper, which I presented only in abstract. There is much reason to feel enthusiastic about the future possibilities of gynecologic organotherapy but not much to inspire pride as to its accomplishments up to the present time.

"The Sleepy Arteries."—On what grounds the tortuous intracranial segments of the internal carotid arteries, whose branches enter the rete mirabile, came to be called "the sleepy arteries" is lost in antiquity, but for some reason or other the idea has prevailed that the function of sleep was ascribable to this region. There seemed to be something more in the idea than pure conjecture, but just what the mechanism of sleep and its alternate phase of waking might be was undetermined. Among theories innumerable, that there may actually be a diencephalic center for the process has been claimed, and the recent demonstration by Hess (1929) of a definite hypothalamic area in the cat stimulation of which will promptly induce a condition which is indistinguishable from sleep points suggestively in this direction. Then, too, we have had before us, these past fifteen years, the all too common examples of lethargy associated with encephalitis, a malady whose effects are prone to strike at this particular part of the brain as shown by other symptoms unmistakably hypothalamic in origin. . . . Thus it would appear that pathological sleep, and conversely of course abnormal wakefulness, in all probability are states induced by a disordered function of the hypothalamus.—Cushing, Harvey: Neurohypophysial Mechanisms from a Clinical Standpoint, Lister Memorial Lecture, *Lancet*, July 26, 1930.

ATROPHY OF THE LIVER DUE TO CINCHOPHEN PREPARATIONS [*]

MEYER A. RABINOWITZ, M.D.

BROOKLYN

Except for the report of a case of atophan hepatitis by Worster-Drought [1] in 1923 and a fatal case of liver atrophy due to Weldona tablets demonstrated by Cabot [2] in 1925, actual knowledge of the toxic effect of cinchophen preparations on the liver dates from 1926. In a little more than four years, forty-one cases have been reported. Including my two cases previously reported and seven cases presented here, there is a total of fifty cases with twenty-five deaths and twenty autopsies, confirming the diagnosis of toxic hepatitis and liver atrophy as the cause of death.

It is highly probable that many cases have not been reported, and that many more cases of jaundice and liver atrophy would on careful investigation prove to be due to the previous use of the drug in one of its forms. This has been amply demonstrated by my own experience. The association of a jaundiced state or atrophy of the liver with the use of cinchophen preparations can no longer be considered a mere coincidence.

The discovery of the preceding use of a cinchophen preparation is the only diagnostic point, since symptomatology and pathology in no wise differs from similar parenchymatous damage of other causation. Toxic symptoms may arise while taking the drug or as late as two months after cessation (Cabot). Suspicion must always arise when questioning reveals previous suffering from joint, muscle or nerve pain. It is in the latter conditions that cinchophen preparations are being so much used. As a result of the extensive advertising claims as a safe analgesic, these preparations are being indiscriminately dispensed in tremendous amounts over the drug counter on request of the layman. Nothing can be further from correct than Hanzlik's [3] statement that, "since the [toxic] symptoms of cinchophen and its ethyl ester and neocinchophen are identical with those of salicyl, no further description is necessary," or Barbour, Lozinsky and Clements' [4] opinion that cinchophen appears to be devoid of side-actions.

CHEMISTRY

Cinchophen, chemically 2-phenyl-quinoline-4-carboxylic acid, was introduced about 1908. Rotter [5] states that it is excreted in the urine as hydroxyl-phenyl-quinoline-carboxylic acid and is therefore not decomposed in the body but excreted after slight oxidation. According to Willcox,[6] the toxic action arises from the quinoline nucleus, consisting of the benzene and the pyridine rings, which yield the toxic ring of free benzene. It is known that atoquinol, arsphenamine and trinitrotoluene all contain the benzene ring and are all capable of producing liver atrophy. Sollmann [7] says that benzene is relatively resistant to decomposition, only a little being oxidized and forming phenols and acids. Sutton [8] states that neither benzene nor phenol produces jaundice in overdoses, but that the nitrophenols (dinitrophenol, trinitrophenol or picric acid) and the nitrobenzenes (nitrobenzol and trinitrotoluene) all produce liver damage. He further believes that the liver is concerned in the decomposition of these products and that under certain conditions the oxidation of the quinoline nucleus produces highly toxic nitro compounds.

PREPARATIONS

Phenyl-cinchoninic acid, atophan, novatophan, atophanyl, diiodoatophan, biloptin, oxyliodide, quinophan, agotan, neo-cinchophen, phenoquam, leucotropin, atophan-urotropine, fantan, iriphan, tolysin, weldona and farastan are all congeners of cinchophen. Atoquinol (atochinol) is a derivative of cinchophen.

PATHOLOGIC AND CLINICAL PICTURES

The amount of degeneration and compensatory regeneration of liver tissue varies with each individual case, thereby producing different clinical pictures. Transitional stages between reversible and irreversible liver damage are possible. So-called catarrhal jaundice has been shown by Eppinger and others to be mild hepatitis ending in recovery. When greater degeneration, necrosis and destruction of liver cells occurs, the condition might be called hepatolysis. When the destructive process is quite extensive, it might be spoken of as liver atrophy. For a more complete description of the various pathologic and clinical pictures under discussion, the reader is referred to my [9] original paper on toxic hepatitis following the use of atophan. These pathologic and clinical states probably do not differ in any way from similar states due to other etiologic factors, and depend entirely on the relative amount of atrophy, regeneration, cirrhosis and nodular hyperplasia. With longer duration, opportunity for regeneration with cirrhosis and nodular hyperplasia is given. There is great tendency to development after tonsillectomy and to fatality soon after exploratory laparotomy, due to surgical trauma, anesthesia and enforced starvation. Clinically there is no evidence of malignant neoplasm. Common bile duct stone is easily excluded when jaundice appears without pain and there is no past history of indigestion or colic. Knowledge of the selective affinity of cinchophen for the liver, the history of its use, and the absence of any other cause for the appearance of jaundice suggests the diagnosis. Numerous postmortem studies have established the truth of these statements.

CASES REPORTED IN THE LITERATURE

A man,[1] aged 59, received 18 Gm. of atophan during twelve days. When he developed urticaria, he stopped the drug for three weeks; then after again taking 0.5 Gm., he developed urticaria the next day and jaundice ten days later which lasted several weeks with recovery. This is the first case to be described in the literature.

A man,[2] aged 42, took three packages of weldona during six months. Two months later the patient had pains, colic, jaundice and indigestion. A physical examination revealed the liver just palpable, bile in the urine in five out of seven examinations, clay colored stools and a negative Wassermann test. Roentgenograms were practically negative The liver became smaller; ascites, some edema, hematemesis and pigmentation developed. There was no fever. The patient died three months later. Cabot mentions "having had an extraordinary series of cases of acute yellow atrophy in patients who have been taking this medicine called weldona." Postmortem examination revealed: acute toxic atrophy of liver, slight secondary cirrhosis, gastro-esophageal varices, ascites, hydrothorax, left serofibrinous pleurisy, edema of the legs and hemorrhages. This case has escaped the attention of those who have hitherto written on this subject. According to advertisements, weldona is stated in The Journal to contain neocinchophen, magnesium carbonate and cascara.[10]

A woman,[11] age not stated, took 5 cc. of atophanyl intravenously fifteen times; she stopped for three days, then took 0.5 Gm. of atophan three times daily for a month. She stopped the drug by mouth because of indigestion, then took some more injections followed by 0.5 Gm. of atophan twice daily for one month—a possible total of 83 Gm. Jaundice occurred, with recovery in several weeks. Not aware of Worster-Drought's and Cabots' cases, Klinkert erroneously believed his to be the first case of liver damage to be reported.

A woman, aged 55, took 70 Gm. of atophan, developed marked urobilinuria without jaundice, and recovered in four weeks. This case does not properly belong in this series, since the author is tabulating only severe cases of toxic action on the liver—such as have developed jaundice.

Langdon-Brown [12] reports two deaths due to atoquinol and states that he knows of two other fatal cases. Atoquinol is chemically allyl-phenyl-cinchonin ester and, though differing materially from atophan, contains the same toxic principle.

Graham [13] gives the details of these two deaths reported by Langdon-Brown. A woman, aged 69, took 12 Gm. of cinchophen weekly for ten weeks. She developed anorexia, vomiting and jaundice; some bile was found in her stools. The patient died the eighth day after admission to the hospital. An autopsy was performed. The other patient was a woman, aged 36, who took 130 Gm. of atoquinol within a period of five months. She stopped for one month and then took 22 Gm. The patient developed jaundice and died in ten days. There was no autopsy.

Evans [14] reports three cases, the age and sex not stated, due to atophan, each patient receiving about 15 Gm.—one case occurring on two separate occasions, once after only 1 Gm. All the patients recovered. He states that all preparations are equally toxic.

Glover [15] reports a case developing after ten atophanyl injections. The patient recovered.

A man,[16] aged 69, received 6 Gm. of atophan inside of one week. A few days later he became jaundiced. He was ill twenty-eight days and died. There was no autopsy. Willcox mentions, without giving any data, two other cases with recovery.

A woman,[17] aged 63, took 200 Gm. of atophan during four and one-half months. After she had been taking the atophan for three months she developed vomiting, and later jaundice. She died in coma on the tenth day of the jaundice. A postmortem was held.

A man,[18] aged 60, took 80 Gm. of atophan inside of two and one-half months. He developed ascites; he was ill three months and recovered.

A woman,[19] aged 31, received an intravenous injection of 5 Gm. of diiodoatophan (biloptin, 50.7 per cent iodine) for cholecystography, cholecystectomy for cholelithiasis and chronic cholecystitis next day. There were no stones in the hepatic or common bile duct and no injury to the common bile duct. The patient developed jaundice two days later; she was ill twenty-six days and discharged with slight jaundice and advanced anemia.

A woman,[20] aged 21, received an intravenous injection of diiodoatophan, developed toxic hepatitis the same day, and died ten days later. A postmortem was held.

A man,[20] aged 60, received diiodoatophan; toxic symptoms developed the next day. The patient recovered.

A patient [21] received diiodoatophan; toxic symptoms developed the next day. The patient recovered.

A woman,[22] aged 56, received diiodoatophan; symptoms developed the same day. The patient died. A postmortem was held.

A *man,[23] aged 32, received diiodoatophan; toxic symptoms* developed two days later. The patient recovered.

A man,[24] aged 54, took atophan in large amounts for a long period; after one month toxic symptoms developed. A laparotomy revealed no gallstones. There was atrophy and cirrhosis of the liver. Death occurred two days later. An autopsy was held.

A woman,[25] aged 52, was given 18 Gm. of atophan. When jaundice developed, the drug was stopped. Another physician represcribed atophan and the jaundice reappeared. The illness lasted six weeks. The patient recovered.

Toxic symptoms developed in a patient [25] after several tablets of atophan were taken. The patient recovered after an illness of forty days.

A woman,[25] aged 52, took forty-eight tablets of atophan. She recovered.

A man,[9] aged 33, took about 15 Gm. of atophan during five months. He recovered after an illness of three months.

A man,[9] aged 39, took 13 Gm. of atophan during about ten days; he was ill four weeks and recovered.

A man,[26] aged 47, took atophan, the amount and duration not stated, and died of acute yellow atrophy. An autopsy was held.

A woman,[27] aged 65, took a total of 60 Gm. of atophan within four weeks. Jaundice developed; she recovered in five weeks.

A woman,[28] aged 55, took large doses of atophan during six months. Jaundice appeared two weeks after the drug was stopped; the illness lasted one week, terminating in death. An autopsy was held.

A woman,[28] aged 55, took atophan for periods of three days with four day intervals, together with sodium bicarbonate during eight weeks. After an illness of five weeks the patient died. An autopsy was held.

A woman,[29] aged 55, took an atophan tablet three times daily for three weeks and died of acute yellow atrophy of the liver. *The case came to a coroner's inquest. Mention is also* made of another case of acute yellow atrophy due to atophan reported two months previously at the Liverpool Medical Society.

A woman,[18] aged 27, took at least seventy-five tablets of cinchophen over an unstated period, developed nausea, vomiting, constipation, urticaria, jaundice, small liver, ascites and died two and one-half months after the onset of jaundice following a Talma operation. A postmortem was held.

A woman,[30] aged 29, unmarried, took salicylates and atophan tablets. During this time she developed angina complicated by phlegmon from which she recovered without operation. Jaundice developed at the end of three weeks of atophan usage, with recovery at the end of one month.

A woman,[31] aged 27, took a total of 117 Gm. of cinchophen in two periods during two months. Jaundice disappeared after two months.

A woman,[32] aged 45, received atophanyl intravenously during a period of twenty-five days, followed nineteen days later by progressive jaundice, bile in the urine, enlarging liver, icteric index as high as 120 and later ascites. The patient recovered after a three months' illness.

A woman,[33] aged 37, suffered with toxemia in a previous pregnancy, followed by a run-down condition and aches. After about one year of an undetermined amount of atophan, indigestion and pruritus developed; two weeks later jaundice, epigastric and lumbar pain developed. Jaundice rapidly cleared up in three weeks. A cholecystogram was negative. Ten weeks later there occurred indigestion, vomiting, a slight ache in the epigastrium, jaundice, pruritus, erythema, enlarged spleen and fulminating toxemia. The patient died nineteen days later. A postmortem disclosed acute yellow atrophy.

A *man,[34] aged 55, given only 6 Gm.* of atophan within two days was ill three weeks. He recovered.

A woman,[35] aged 48, took 600 tablets of oxyl iodide (each tablet is 3 grains [0.2 Gm.] and contains 83.3 per cent cinchophen) during a period of seven months. Death from acute yellow atrophy after an illness of nine days was revealed by a postmortem examination.

A woman,[36] aged 20, took cinchophen since January; jaundice developed in May, a week after tonsillectomy, and lasted six weeks. With the recurrence of arthritis, large doses of cinchophen plus oxyiodide were given followed by fever, purpura, enlarged liver and enlarged spleen. The patient died. Postmortem examination revealed toxic cirrhosis of the liver.

A *woman,[36] aged 46, repeatedly took* large amounts of cinchophen over a period of three years. Death occurred on the tenth day after the onset of jaundice and cholemia. An autopsy was held. Reichle states that at the conference in the City Hospital in which one of his cases was presented, several physicians reported that they had seen jaundice during the period of medication with cinchophen.

A woman,[37] aged 52, had an epithelioma of the cervix of the uterus which extended onto the posterior vaginal wall. Radium treatments were given. From 1923 to 1929 the patient enjoyed excellent health. During the summer of 1929 she suffered with neuritic pains in the right thigh for which she took from one to three tablets of cinchophen daily for six weeks. She finally discontinued the medicine because of the appearance of nausea and vomiting, which developed one month after she had begun to take the drug. A week after she had stopped taking cinchophen, jaundice appeared suddenly, concomitantly with an attack of diarrhea which lasted only a day. The jaundice was intense from the beginning and did not fluctuate. There was no purpura or pruritus. *Her condition grew steadily* worse and she died sixteen days after the onset of the jaundice, with terminal hyperpyrexia and signs of bronchopneumonia. At postmortem examination the liver weighed only 903 Gm. Obstruction of the right ureter with hydronephrosis, was present, as the result of the previous malignant condition.

ADDITIONAL CASES

Case 1.—L. C. K., a woman, aged 37, whose father suffered *from asthma, had had one pregnancy followed by hysterectomy* for uterine fibroids nine years before. She had had aches and pains particularly in the feet for four years, and she was overweight. Her basal metabolism was —10. She was prescribed thyroid, ½ grain (0.03 Gm.), and cinchophen, 2 grains (0.13 Gm.), three times daily, which she took on and off without untoward results for two months. Basal metabolism was then —6, fasting blood sugar 79 mg. per hundred cubic centimeters. Thyroid, ⅔ grain, (0.04 Gm.) and cinchophen, 2 grains, three times daily were then given. One week later she felt tired and languid; two and one-half weeks later her urine became dark, soon to be followed by jaundice with itching. The liver was palpable, and she had lost 12 pounds (5.4 Kg.) *in the last three months.* The *spleen was never palpable.* The gallbladder a short time previously had been negative to cholecystography. On a high carbohydrate diet with insulin injections, jaundice rapidly disappeared; the liver was no longer palpable. The illness lasted about two months. The patient recovered and has remained well.

Case 2.—(service of Dr. Adolph Bonner, Jewish Hospital)—A woman, aged 31, had had asthma and hay-fever *a year before* she was seen, for which she received desensitizing injections. One month before admission she had a febrile upper respiratory infection which was followed by aches and pains in the back and shoulders, for which she was advised a 7½ grain (0.5 Gm.) tablet of atophan three times daily; she took a total of 20 tablets. In a few days after beginning the drug she

developed weakness, followed in about two weeks by jaundice and dark urine containing a trace of sugar. She was admitted to the wards. The liver edge was 4 cm. below the right costal margin. Jaundice and itching became marked; there was no fever. The stools were clay colored but showed traces of bile from time to time; the icteric index was 70 on admission; a tetraphenolchlorophthalein test for the liver damage was positive. The blood Wassermann reaction was negative. Fasting blood sugar was 100 mg. per hundred cubic centimeters. Urine bile was present. There was no leucine or tyrosine. The gallbladder could not be visualized by intravenous injection of dye. No colics occurred. On admission, menstruation was overdue one week. The uterus gradually enlarged. A diagnosis of pregnancy was made, and because of her hepatic condition, therapeutic abortion was done. An examination of the curettings showed that pregnancy was present. Jaundice gradually cleared up, and she was discharged completely recovered in seven weeks.

Case 3.—(service of Dr. Soresi, Greenpoint Hospital).—G. C., a man, aged 45, suffered from generalized aches and pains for one month. Atophan was begun, Sept. 30, 1927, with a dosage of one tablet of 7½ grains three times daily. Feb. 8, 1928, four months later, this dosage was increased to a tablet every three hours. During this period (October 21, 25, November 2, 9, 21 and December 28) he had also received six injections of 5 cc. of Lactogen—a sterilized milk preparation—as parenteral protein therapy. December 28, the injection was followed by shock and he was admitted to the hospital and discharged the next day with the advice to continue the atophan. *February 17, it was noted that the patient was very weak and* at times he became unconscious for as long as three quarters of an hour. He had lost 55 pounds (25 Kg.) in the last year, *suffered epigastric pressure,* and was markedly jaundiced for four days. He was readmitted to the hospital. Ascites and hydrocele were present; the urine showed bile; the blood count was 19,000 white cells, *of which 80 per cent* were polymorphonuclears. There was no fever. The patient died six days later, and postmortem examination revealed normal pancreas, gallbladder and biliary passages. The liver weighed 1,100 Gm., showed marked pericapsular adhesions, cut with resistance, and on section revealed nodular hyperplasia with portal cirrhosis. There was *no evidence of cholangeitis.* The spleen weighed 225 Gm. and was normal. There were patches of purulent peritonitis.

The following case reports, heretofore unpublished, are from the service of Dr. Leo Kessel [38] of Mount Sinai Hospital, New York, Dr. Max Grolnick [39] and Dr. A. A. Stone [40] of Brooklyn, to whom I am indebted for the privilege of presentation and publication at this time.

Case 4.—(service of Dr. Leo Kessel [38]).—C. K., a woman, aged 51, complained of epigastric distress after meals for the past year, relieved by sodium *bicarbonate; she tired easily,* was markedly constipated, and suffered from severe pain in both knees, which became worse on motion. The diagnosis was chronic infectious arthritis, nasopharyngitis, infected tonsils and obesity. A tonsillectomy was performed, March 1, 1929. She was put on sodium salicylate and iodides, and atophan 5 grains (three times a day?) with instructions to take the prescription until the pain ceased. At a subsequent visit the medication was renewed. After four weeks the patient was bedridden and jaundiced. *For two days* there was severe abdominal pain in the right upper quadrant and epigastrium. She was admitted to the hospital, April 20. The last four days she had been restless and her eyes were glazed. There was twitching, followed by coma of twenty-four hours' duration. The patient was comatose and deeply jaundiced, with pitting edema of the ankles, and the liver was small to percussion. A provisional diagnosis of acute yellow atrophy of the liver was made. The blood count was: hemoglobin, 85 per cent; red blood cells, 4,700,000; polymorphonuclears, 90 per cent; platelets, 300,000; bleeding time, three minutes, and coagulation time, two minutes. A tourniquet test was negative. The blood pressure was 95 systolic and 50 diastolic. She died within twenty-four hours after admission. The autopsy observations were: subacute yellow atrophy of the liver, jaundice, edema of the ankles, parenchymatous degeneration of the heart and kidneys, tracheitis and bronchitis, obesity and hemorrhages in the skin and mucous membranes of the intestine, trachea and bronchi.

Case 5. (service of Dr. Leo Kessel [38]).—W. W., a patient, aged 26, married, after having constant indefinite complaints *for two years, developed six weeks before admission a fleeting* speckled rash, migratory polyarthritis, slight fever, chilliness and slight precordial pain. Cough developed three days before admission. Examination revealed good nutrition, infected tonsils and slight fever; the spleen was enlarged 3 fingerbreadths below the costal margin; the liver felt 1 fingerbreadth below *the costal margin; there was no swelling* or tenderness of the bones or joints; there were a few erythematous areas over the face, chest, hands and anterior area of the elbows, and there was a diffuse generalized lymphadenopathy. The blood count was: white blood cells, 11,700; polymorphonuclears, 82 per cent. Mellitensis agglutination and blood cultures were negative; a roentgenogram of the chest showed no abnormality; the urine on admission was negative. Atophan was given to relieve the joint pains, the patient receiving about 70 grains (4.5 Gm.) in all. *Tonsillectomy* was performed, followed by sudden jaundice, fever and a poor general condition. A liver function test showed a dye retention of 100 per cent in thirty minutes; the sedimentation time was two hours. The temperature rose to 105 F. and the patient died ten days *after the onset of the* jaundice, in spite of high carbohydrate diet and repeated infusions of dextrose. It was felt that the temporary deprivation *of food preceding the tonsillectomy was a factor in making the* liver more susceptible to the effect of the atophan.

May 29, 1930, Dr. Kessel, two of whose cases have been *reported, wrote: "I have seen a total of thirteen cases of* atophan poisoning."

Case 6 (patient of Dr. Max Grolnick [39]).—A woman, aged 45, who had never been pregnant and had suffered numerous infections, especially of the upper respiratory tract and the genitalia, developed arthritic pains for which she took weldona tablets. This was followed by backache. Two weeks later she again took six weldona tablets, followed the next day by backache, epigastric distress, bile in the urine, jaundice and clay-colored stools. *The taking of these tablets had been preceded* by intravenous injections of "some preparation made from the joint fluid" by another physician. Examination revealed obesity and jaundice. There was no fever. The liver was tender but not enlarged. There was bile in the urine: *the stools were* acholic; red cell hemolysis began at 0.32; the icteric index was 57. A Wassermann test was negative; gallbladder visualization was at first negative; *after recovery it was normal.* There was a rapid improvement and the patient was discharged in five weeks.

Case 7 (patient of Dr. A. A. Stone [40]).—A woman, aged 39, treated for six months with large doses of atophan for arthritis of the hip, developed progressive jaundice. An exploratory laparotomy was done *and the patient died on the table after* an illness of four months. Very small cirrhotic atrophy of liver (gross and microscopic) was found.

PREDISPOSITION

I believe that only under certain conditions does the liver *become sensitized to the toxic action of the* cinchophen preparations. The duration of its use and the total amount ingested or otherwise introduced into the body have been found to vary in each case, one person developing ill effects after a comparatively small amount, intravenously or by mouth, while another may not develop it until after long continuous use. De Rezende's second patient received only about 3 Gm., one of Kessel's patients, 4.5 Gm.

Predisposed are those with gallbladder disease, cirrhosis of the liver, pregnancy, chronic alcoholism, chronic nephritis, those who in the past have suffered from liver disease associated with jaundice, and those showing other evidences of cinchophen intolerance. The drug appears particularly dangerous in states of hepatic damage accompanying starvation, malnutrition, cachexia, chronic infection or tonsillectomy, after fevers, or in conditions favoring decreased glycogen content of the liver cells. Unger and others have definitely proved that under these conditions there is greater tendency to liver degeneration. Cinchophen, according to Taubmann,[41] is excreted in the bile and inhibits carbohydrate digestion, thus further favoring decreased liver glycogen storage.

[38] Kessel, Leo: Personal communication to the author, May 1929.
[39] Grolnick, Max: Personal communication to the author, May, 1929.
[40] Stone, A. A.: *Personal communication to the author,* May, 1929.

A closer study leads to the suspicion that sensitization of the liver to protein, whether by surgical trauma, inhalation, ingestion, or parenteral injection (milk preparations such as lactogen and aolan or vaccines) renders it most susceptible to the toxic damage of cinchophen. Experiments are now under way to determine this point.

PRECAUTIONS

In spite of all the precautions hitherto advised, cinchophen therapy has proved dangerous. Intermittent use to avoid retention of dangerous amounts proved of no avail in cases reported by Klinkert, Langdon-Brown, Lowenthal and myself. Neither the associated intake of large amounts of fluid to aid more rapid elimination nor the use of large doses of sodium bicarbonate are certain guarantees. Large amounts of readily assimilable carbohydrates, given with small amounts of insulin, might protect the liver by restoring its glycogen content. It has been proved that carbohydrate without insulin is insufficient for this purpose. The intravenous use of cinchophen appears dangerous.

EARLIEST SIGNS OF TOXICITY

The drug should best not be used in ambulatory cases, as the earliest signs are thus likely to be overlooked. These warning signs are malaise, anorexia, nausea, vomiting, indigestion, pruritus, urticaria, albuminuria, pains about the liver, subicterus, tenderness of the liver, rise in the bilirubin content of the blood, bile pigment in the urine, marked urobilinuria, marked depression of the vasomotor system, purpura, scarlatiniform rash, or edema with fever.[42]

TREATMENT OF LIVER DAMAGE

With the earliest appearance of toxic phenomena, the drug should be stopped and the patient hospitalized. Dextrose by mouth or rectal drips in large amounts should be given, and from 5 to 10 units of insulin, three times daily ordered. If the symptoms are at all severe, intravenous injections of dextrose in large amounts should be given slowly as well. Proteins in the diet should be reduced to minimal amounts, as the liver is no longer fully capable of detoxicating the products of protein metabolism. Adler, according to Weigeldt,[43] advises the use of a combination of lactic acid, saline solution, dextrose and insulin together intravenously in the severest cases of liver atrophy, with the object of sparring for time until the necessary regeneration of the liver tissue occurs. As a last resort, Petermann of Berlin advises surgical drainage of the hepatic or common bile ducts. I have employed duodenal instillations of magnesium sulphate solutions, together with high carbohydrate diet and insulin injections.

CONCLUSIONS

1. Cinchophen preparations may produce liver damage of varying severity to fatality.

2. This danger cannot be avoided by small doses, intermittent use, large amounts of fluid or associated use of sodium bicarbonate.

3. Since cinchophen is not a specific for arthritis, gout, myositis, neuritis or allied states, indiscriminate use and counter prescribing is dangerous, and the drug or its congeners should not be used in cases difficult of careful control and observation.

4. All cinchophen preparations and congeners should have their content advertised and noted on the container in which they are dispensed.

5. Protein sensitization of the liver may be responsible for the subsequent production of the liver damage by cinchophen.

6. Research work is needed to determine the factors in the production of liver damage and to prevent this dangerous effect.

651 St. Marks Avenue.

ABSTRACT OF DISCUSSION

Dr. Torald Sollmann, Cleveland: Time does not permit more than a brief glimpse of the more scientific problems that are suggested by Dr. Rabinowitz's presentation: the attempt to protect the liver by carbohydrates, reinforced by insulin, sounds reasonable. Its actual efficiency, however, cannot be decided until it is possible to furnish controls and this will probably require animal experimentation. This in turn is difficult because of the capriciousness of the hepatitis.

A hint is furnished by the promptness and frequency of the hepatic reactions from the intravenous injection of di-iodo-atophan (Biloptin) for choleography. This may be in line with the suggestion of Dr. Rabinowitz, that hepatic disorders predispose to cinchophen hepatitis, and suggest the possibility of its experimental production by combination with subeffective doses of other hepatitic agents, such as carbon tetrachloride. If this is successful it will furnish the possibility of testing the treatments. It will give a means for attacking the mechanism of the hepatitis; this may enable us to avoid such reactions.

At present, we are very much at sea. The liver seems to go the even tenor of its way through a great variety of major disturbances of the organism but goes completely to pieces under circumstances which would be considered much less violent; particularly in response to a miscellaneous variety of poisons. It would be interesting to learn how this is correlated with chemical structure. The relation is probably not directly to the benzene nucleus, as was suggested in the speculation of Willcox; at least, the action has not been demonstrated for most of the benzene derivatives and is much more marked with some aliphatic compounds, such as chloroform, carbon tetrachloride, and with phosphorus. It is quite possible, however, that these various hepatites may differ in nature as well as in causation.

Dr. Philip S. Hench, Rochester, Minn.: In the past, one has felt fairly secure in giving alkalis and rather large amounts of water when using atophan or cinchophen, but apparently these measures are not sure safeguards. Four patients have been brought to the Mayo Clinic with acute yellow atrophy of the liver. These patients had taken cinchophen elsewhere, not in large amounts, for fairly short periods of time, and on physicians' prescriptions. Two had had associated treatment with alkalis. One had used oxyliodide, one had had oxyliodide and another product containing cinchophen. Two had felt safe in using only the so-called best brand of cinchophen. At least one other patient had toxic hepatitis but recovered. Our patients did not relate, after careful questioning, any past experience that would lead us to suspect that their livers had been injured earlier in life, nor at necropsy did the microscopic examination reveal any evidence of previous hepatic disease. Two years ago, Dr. E. V. Allen and I, in spite of ample evidence of minor disturbances and occasional serious results, nevertheless gained the impression, in view of the wide use of this drug, that minor disturbances resulted in only a very small percentage of persons who use it and that but a fraction of 1 per cent die from its use. The review by Dr. Rabinowitz will stimulate the attempt to answer several questions. Why was the toxicity of cinchophen so long unreported? Has there been a change in manufacturing? Are certain products really less toxic than others? Are certain batches of the drug itself toxic, or do only certain patients illustrate altered catabolism? If continued use of cinchophen is to be advocated, these questions should be answered. Many patients have large tolerance. One patient whom I had under observation for fifteen and a half years had taken from 40 to 90 grains (2.5 to 6 Gm.) of cinchophen daily, with no apparent discomfort or disability. Two and a half years later, under the observation of Dr. Haden of Kansas City, he still insisted on taking cinchophen for his arthritis. Hence, his amazing tolerance has continued for a period of eighteen years, which almost equals the entire history of treatment by cinchophen.

DR. ALEXANDER LAMBERT, New York: The peculiarity of the acute yellow atrophy due to cinchophen is so striking when one sees a case that I feel constrained to report one that occurred in Bellevue about two years ago, in the ordinary practice of a medical ward. The patient came in, pale, but under the paleness there was an increasing jaundice. He reported that he had had rheumatism, meaning pain in some joint or somewhere, and that he had taken what was to him a well known rheumatic remedy, the Harrell "Rheumatism Cure," which had been given to him by a neighbor, which had done that neighbor a great deal of good. He had taken evidently large amounts because he had taken it for eighteen months or two years. His jaundice rapidly increased and his fever rapidly increased. He died of acute yellow atrophy in a few days. I wrote to the American Medical Association and found that this rheumatic remedy contained large amounts of cinchophen and it was one of those cinchophen acute yellow atrophies. The reason that I think acute yellow atrophy is much less often diagnosticated is that the beginning of acute yellow atrophy is not of the stormy type that physicians have been taught to expect and, further, that jaundice in the majority of cases is diagnosticated as acute catarrhal jaundice. I know that this diagnosis must be universally taught because in the Fourth Division of Bellevue our interns come from all over the country and the invariable diagnosis of a slight jaundice by all kinds of interns taught by all kinds of teachers for many years has been acute catarrhal jaundice, which is the last thing usually that happens to a jaundiced patient.

DR. L. G. ROWNTREE, Rochester, Minn.: I wish to ask one question. What are we going to do about it? I have seen these cases in Rochester, and have seen the patients die despite everything we could do. I saw the patient, referred to by Dr. Hench, who had then been taking cinchophen for thirteen years. He asked me at the time about its toxicity. I told him I knew of no one who had taken so much. He insisted on taking it, as he said that it was the only thing that gave him relief from pain. I am asking the question as to whether there is in existence any mechanism for having this problem properly investigated. It would seem to me the most likely thing would be to have it taken by the officers of this section to the House of Delegates for consideration. I believe it is a sufficiently important problem to the health of the people to merit thorough investigation.

DR. WILLIAM S. COLLENS, Brooklyn: Dr. Sollmann recommended a scientific investigation of Dr. Rabinowitz's suggestion in regard to therapy. I should like to state the results of some experiments which Dr. Murlin and I conducted at the University of Rochester about two years ago that have a definite bearing on the therapeutic value of dextrose and insulin. In some experimentally produced degenerative changes in the liver by means of ligation of the hepatic artery we studied the value of dextrose intravenously in these dogs, using the respiratory quotient as a criterion or an index of its utilization, and we found that dextrose was not at any time utilized unless insulin was given along with it. That fairly confirms scientifically we think the suggestion that Dr. Rabinowitz makes about the value of insulin when dextrose is administered even to nondiabetic subjects. We have since had occasion to carry on the same experiments in patients who had cholecystectomies performed and who also showed, on resection of wedge-shaped sections of the liver for histologic studies, definite hepatitic changes such as were reported some years ago by Dr. Evarts Graham of St. Louis. We found there again that the respiratory quotient determinations following intravenous dextrose did not show any rise unless insulin was administered. This fairly well proves the value of Dr. Rabinowitz's suggestion that insulin administered with intravenous dextrose has a protective effect on a liver which is definitely degenerated.

DR. M. A. RABINOWITZ, Brooklyn: In answer to Dr. Rowntree's question, I had omitted part of a paragraph of my paper on the treatment. Adler, according to Weitgeldt, advises the use of a combination of lactic acid, saline, dextrose and insulin together intravenously in the severest cases of liver atrophy, with the object of sparring for time until the necessary regeneration of liver tissue occurs. As there is no organ in the body that has such capacity for regeneration as the liver, sparring for time might make it possible to save the patient. As a last resort, Petermann of Berlin advises surgical drainage of the hepatic or common bile ducts. This does not appear to me from a medical point of view as a most rational procedure, but he does report good results in severe liver atrophies of other causation.

STUDIES IN INFANT NUTRITION

VI. LACTOSE AND A MALTOSE-DEXTRIN PREPARATION *

JESSE R. GERSTLEY, M.D.
Attending Pediatrician, Michael Reese Hospital; Associate in Pediatrics, Northwestern University Medical School
CHICAGO

The studies have been carried on for eight years. They fall into two groups, chemical and clinical. The chemical work was done under the supervision of Dr. Chi Che Wang with the technical assistance of Miss Agnes A. Wood. All cow's milk was boiled one minute. The babies were normal infants more than 2 weeks of age, kept in a separate nursery, with special nursing provided by the hospital administration and the training school. Thus the infants escaped most of the parenteral infections so prevalent in any infants' ward. Experiments were never carried on when the babies were losing weight or seemed sick in any way.

PURPOSE OF THE WORK

According to the early theories of Finkelstein and L. F. Meyer, a diet containing excessive carbohydrate in cow's milk favored the development of diarrhea and nutritional disturbance. The mechanism was simple. Bacteria normally present in the intestine fermented the carbohydrate into various products, among these being lower volatile fatty acids, such as acetic and formic. Irritation of the intestine by these acids resulted in diarrhea, which in turn led to a disturbance of nutrition.

These theories found universal acceptance. Surprisingly little scientific work was done to confirm them. Ten years ago I thought it would be a simple matter to subject the hypothesis to chemical proof. One could prescribe a diet low in carbohydrate and determine the acids in the stool. Then the carbohydrate could be increased and the acids again determined. Unquestionably the increased carbohydrate would lead to increased intestinal fermentation and

* From the Sarah Morris Hospital for Children, the Otto Baer Fund for Clinical Research and the Nelson Morris Institute for Medical Research of the Michael Reese Hospital.

increased acid output. The whole theory would then become a fact. The ideal carbohydrate for such experiments would, of course, be lactose.

LACTOSE IN INFANT NUTRITION

Discovered in the seventeenth century, lactose remained unmolested for 200 years. Then it became the target of the pediatricians. Before Escherich,[1] in 1886, had started his pioneer work on intestinal fermentation, Jacobi[2] had voiced his fear of the sugar because of the ease with which it changed to the dangerous lactic acid. From that time, although it is the sugar found normally in breast milk, its reputation in artificial feeding sank lower and lower.

Early writers[3] were not so concerned with its fermentability as with the impurities it contained. This fear was voiced by Brush[4] at a meeting of this section held at Nashville, Tenn., in 1890. He wrote, "Something must be wrong with some types of lactose because one does not find it in the urine of the breast fed." He found it in the urine of three artificially fed children. The metabolic conception of nutritional disease developed long afterward. Better methods of isolating lactose, devised by Soxhlet in 1893, did away with this objection.

New dangers were ascribed to lactose by Finkelstein and Meyer,[5] in that it exerted a specific pyrogenic action on the body. Schlutz,[6] in 1912, confirmed these experiments when lactose was given with sodium chloride.

At present it is safe to state that lactose is feared by all pediatricians chiefly on account of the ease with which it ferments in the intestine. Every textbook contains the same statement (Escherich, Czerny-Keller, Langstein and Meyer, Finkelstein, Feer, Heubner, Brennemann, Holt, Grulee). Individual studies[7] have offered the same conclusions, that lactose may be used in a normal infant but only with extreme care. A few writers[8] speak an occasional kind word for the sugar but Morse and Talbot, who certainly are the most friendly, warn that it should never be used in amounts over 7 per cent.

Clinical experience plus uncritical acceptance of the teachings of Escherich seem to have influenced most opinions.

Up to the latest writings the question is still disputed. Barenberg and Abramson[9] in the clinic of Alfred Hess have been daring enough to report excellent clinical results with lactose in infants more than 3 months of age. On the other hand, Paffrath[10] gave children solutions of various sugars and found lactose alone was responsible for diarrhea. Marriott in his new book reiterates the warning that lactose "cannot be used with as great safety or fed in as large amounts as other carbohydrates."

The preponderance of evidence then suggests that if one wishes to study nutritional disturbance arising from intestinal fermentation and diarrhea, lactose should be the ideal carbohydrate to use.

CHEMICAL RESULTS

These studies,[11] so simple in their inception, have taken ten years and are still under way.

Charts of the entire chemical and clinical study have been displayed in the scientific exhibit.

Time permits the demonstration of only a few to show some of the high points of the work.

With the stools of normal breast-fed infants taken as a standard, studies have been made of the stools of clinically normal infants while on cow's milk feedings, as well as of the stools of diarrheal children, both on breast and on cow's milk.

The stools of infants fed on whole cow's milk, who are clinically normal and do not give a clinical picture of diarrhea, compare as follows with those of normal breast-fed babies:

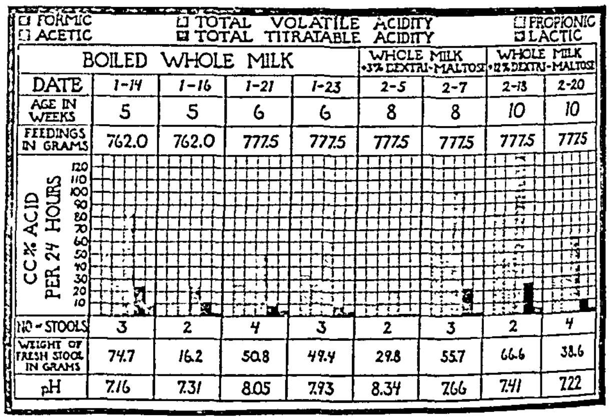

Chart 1.—The influence of the addition of 3 and of 12 per cent of the maltose-dextrin preparation to whole boiled cow's milk on the quantity of feces, the frequency of defecation, the excretion of total volatile acids and their salts, on total titratable, lactic acids and lactates, and on the hydrogen ion concentration, in a normal infant.

The stools of artificially fed babies are of greater weight for the twenty-four hour period. There is a somewhat greater output of lower volatile fatty acids and their salts, with a somewhat lowered output of lactic acid and lactates. The free acid, as shown by the total titratable acidity of the twenty-four hour specimen, is lower. The p_H (which represents "true" acidity) is considerably higher than that of the stools of the breast fed. Infants fed on cow's milk often pass nearly neutral or even slightly alkaline stools.

When infants fed on breast milk develop the clinical picture of diarrhea, they show an increased frequency of stools, with a small increase in their weight. The excretion of volatile fatty acids and their salts is slightly increased, as is also the excretion of lactic acid and lactates. The twenty-four hour figure for "total" titratable acidity is also increased. There is very little change in the p_H, which is the measure of the "true" acidity.

Gerstley, J. R.: Id.: V. Clinical Considerations, ibid. **40**: 27 (July) *1930.*

The stools of infants fed on cow's milk who develop diarrhea show a markedly contrasting picture. There is a great increase in weight of the stools, and a correspondingly great output of volatile acids and their salts, as well as of lactic acid and lactates. The figure for "total" titratable acidity is increased; however, the p_H remains toward the alkaline side, just as it does in normal babies fed on cow's milk. The older clinicians, considering figures for "total" titratable acidity, believed the stools of diarrheal children to be "very acid"; p_H measurements (which give "true acidity" as judged by the hydrogen iron concentration) show this concept to have been erroneous. The stools of infants fed on cow's milk are less acid than those of breast fed infants, whether they are diarrheal or not.

As cow's milk contains only 4 per cent lactose and breast milk 7 per cent, factors other than the *amount* of lactose in the diet determine how much of this lactose shall ferment. Unquestionably the problem becomes *one of factors influencing lactose absorption.*

What changes take place when lactose is added to whole cow's milk?

In a typical case the addition of 3 per cent lactose causes no great change in the picture of stool chemistry, except in hydrogen ion concentration. In infants with no diarrhea the addition of 3 per cent lactose increases the total titrable and lactic acids. Clinically the children seem much happier.

Changing to 12 per cent effects a noticeable chemical change but, to one's astonishment, exactly the antithesis of the one expected. The longer the child is on the mixture, the less is the quantity of acid excreted and the more do the stools resemble those of the breast fed. Apparently the relation of lactose to protein, approximately 4 to 1, like that existing in breast milk, is most favorable to intestinal processes. In my desire to produce diarrhea experimentally by increasing the quantity of lactose in the diet, I was unconsciously bringing about a relation of lactose to protein which proved actually beneficial.

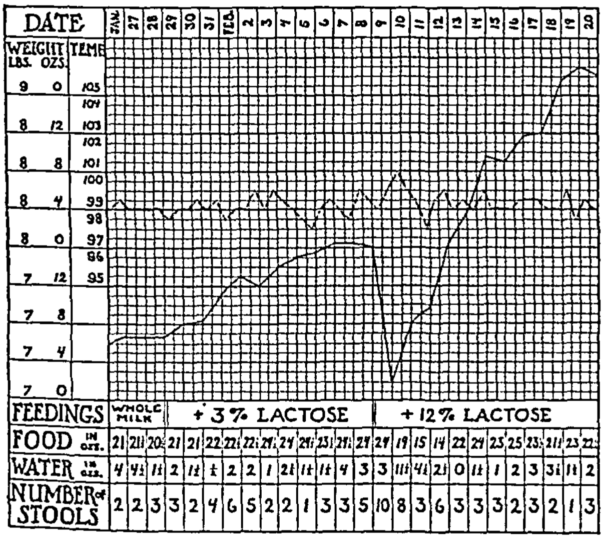

Chart 2.—This and chart 3 show that a diet of whole cow's milk with the addition of 3 per cent and later 12 per cent lactose continued over a number of weeks led to a severe loss of weight but with no diarrhea.

Chart 1 shows the effect of adding a preparation of maltose and dextrin[12] with 2 per cent sodium chloride to whole boiled cow's milk. It is introduced to show the slight effect that this carbohydrate exercises on the stool picture of whole cow's milk. In this chart the differential analysis for volatile acids can be disregarded.

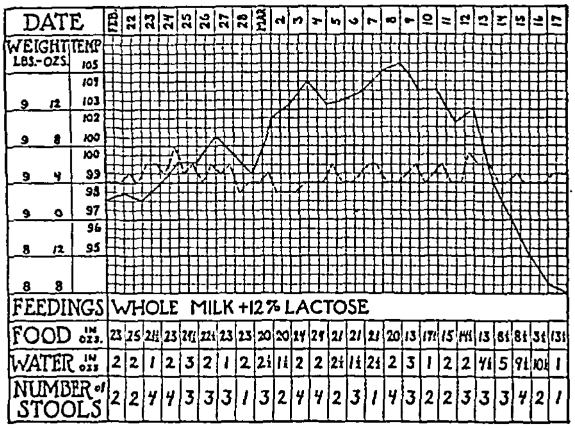

Chart 3.—This and chart 2 show that a diet of whole cow's milk with the addition of 3 per cent and later 12 per cent lactose continued over a number of weeks led to a severe loss of weight but with no diarrhea.

On whole cow's milk the stools are small, contain small amounts of free acid, little lactic acid and lactates, and show a hydrogen ion concentration toward the alkaline. Clinically the baby was constipated.

The addition of 3 per cent of the maltose-dextrin preparation causes little change except some increase in the total volatile acids and their salts.

To our surprise, the addition of 12 per cent of the maltose-dextrin preparation has almost no effect on the total free acid, lactic acid and lactates, stool weight and frequency, and hydrogen ion concentration, while there is a possible increase in the total volatile acids and their salts.

In this respect, the maltose-dextrin preparation is in striking contrast to lactose, and our analyses confirm its constipating alkalizing effect in the intestine.

LATER THEORIES

During the years that these experiments were being conducted, Finkelstein and Meyer modified their views. From clinical observation Finkelstein, in his book of 1921, believes that cow's milk causes a primary injury to the *intermediary metabolism,* and following such injury diarrhea develops as a secondary complication. Thus intestinal fermentation with resulting diarrhea becomes a result of disturbance of nutrition rather than a cause.

CLINICAL STUDIES

Our clinical studies favor the later hypothesis. After being convinced that lactose was not as dangerous as I had thought, and that in a well baby on a diet of whole cow's milk, a proper lactose-protein relationship improved diarrheal stools, I tried feeding a number of infants on whole cow's milk with 12 per cent carbohydrate.

Charts 2 and 3 show the clinical course of such a case. On whole cow's milk with 3 per cent lactose the infant thrived beautifully. A change to 12 per cent caused a temporary upset, but with no change of diet he recovered in twenty-four hours. Then for a period of weeks he became one of the show babies of the hospital. I thought I had discovered the real secret of infant feeding. One day with almost no warning he developed an alimentary intoxication. No parenteral infection could be demonstrated. The diagnosis was confirmed by a twenty-four hour tea diet with a resulting straightening of the weight curve. The critical loss of weight could scarcely have been due to decreased food intake, for complete starvation caused recovery. Of particular importance in this case was the *absence* of diarrhea. Such evidence is almost conclusive that the severest types of nutritional disturbance, even alimentary intoxication, can develop without gastro-intestinal involvement.

---

[12] The preparation used was Mead's dextri-maltose.

Chart 4 shows another striking clinical reaction. This baby had been on whole cow's milk with 12 per cent of the maltose-dextrin preparation for more than a month. Like the baby on lactose, he seemed in the best of health. Following the conclusion of the chemical experiments he was put on a diet of two-thirds cow's milk with 5 per cent of the maltose-dextrin preparation and discharged from the hospital. During the two weeks spent in trying to find a home for him he developed a mild otitis media. This infection, certainly not virulent clinically, precipitated the profoundest nutritional disturbance. Again the severest nutritional reaction is seen occurring without marked gastro-intestinal involvement. These studies certainly favor the Finkelstein hypothesis that injury to the general nutrition often precedes signs of intestinal fermentation.

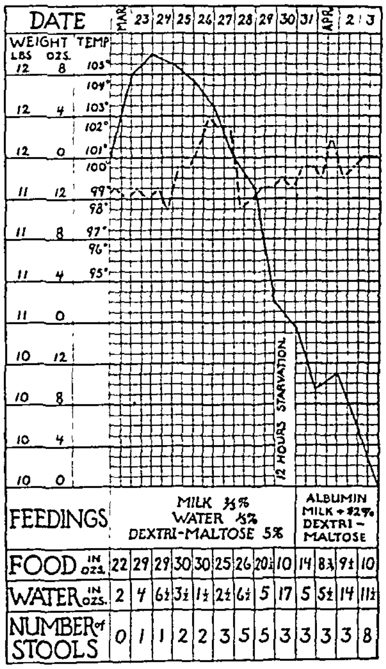

Chart 4.—Alimentary intoxication induced by a very mild otitis media in an infant who had been on whole boiled cow's milk with 12 per cent of the maltose-dextrin preparation over a period of weeks. Diarrhea occurred only as a terminal complication.

COMMENT

The experiments are thus clearly divided into two groups.

Chemical studies have shown that lactose per se does not deserve its bad reputation. It can be given to a normal infant in good hygienic environment without undue risk, even with the additional digestive strain of whole cow's milk. If intestinal fermentation and diarrhea arise, they are not proportionate to the amount of lactose in the formula. Unquestionably some other element of cow's milk, probably by delaying lactose absorption, and thus permitting a greater total bacterial growth and increased fermentation, or by increasing peristalsis plays a great rôle. The relation of lactose to protein seems important. From studies previously reported,[11] parenteral infection plays the greatest rôle of all. Secondary in importance only to parenteral infection in influencing stool chemistry is the child's general nutrition.[11] The amount of lactose in the diet is not nearly as important as the factors which influence its absorption.

In regard to the maltose-dextrin preparation, the analyses of the stool showing low total and lactic acids and hydrogen ion concentration toward the alkaline confirm the clinical observations of its constipating tendency. Its value in true nutritional disturbance is not under discussion. When given to the normal infant in a mixture of cow's milk it results in changes in stool chemistry *further from that of the breast fed than does lactose.*

The second series of experiments, while offering clinical corroboration of some of the theories of nutritional disease, has raised a question which is still unanswered, which I doubt whether the experience of any one observer can answer. Whether the success of lactic acid milk is due to the lowering of the buffer as Marriott claims, or whether the fine curd is a factor as Brennemann recently suggested,[13] in either case the theory of the success of the mixture is in its digestibility. In our work whole cow's milk with carbohydrate seemed to effect a change in the infant's body predisposing to severe nutritional disturbance, and causing him to show the severest nutritional reaction following the mildest parenteral infection. These changes were independent of any gastro-intestinal disturbance. If normal stools can be taken as evidence, our mixtures were digested perfectly.

The addition of lactic acid to milk may make the mixture more digestible, but does it take away any of the factors which in our experiments seem to injure the body? It is significant that while pediatricians in this country discussed the effects of parenteral infections over fifteen years ago,[14] and in Germany long before that, no one fears them as does the St. Louis school. Is it possible that lactic acid milk plus high carbohydrate favors the development of nutritional disturbance following parenteral infection? This is just a thought which has occurred to me and I am putting it as a question. It is a question which cannot be solved except by the combined activities of all of us. The babies I studied were in a hospital. Perhaps if they had been at home with their mothers they would not have sickened on these diets. At any rate, I am bringing up the question in the hope of enlisting cooperation in seeking an answer.

It is interesting to reflect that in our ignorance we have blundered into efficient methods of milk modification. Empirically we keep an approximately favorable carbohydrate-protein ratio and in addition our milk dilutions prevent the dangers of overfeeding.

CONCLUSIONS

The conclusions can be divided into two groups:

A. Chemical studies show that:

1. Lactose added to whole boiled cow's milk does not result in diarrhea with a great increase in the excretion of acids when given to normal infants.

2. The amount of various acids excreted by the intestine does not depend directly on the amount of lactose in the diet but on various factors which are probably concerned in its absorption from the intestine. The relation of lactose to protein in the diet is of great importance.

3. In respect to certain chemical relationships in the stool, lactose seems preferable to the maltose-dextrin preparation.

B. Clinical studies, dealing with the development of nutritional disturbance, favor the Finkelstein hypothesis that cow's milk causes a primary injury to the intermediary metabolism. Should intestinal fermentation and diarrhea develop, they are secondary and incidental to the primary disturbance of body nutrition. The severest nutritional disturbance may exist, even alimentary intoxication, without gastro-intestinal involvement.

ABSTRACT OF DISCUSSION

DR. F. W. SCHLUTZ, Chicago: The carefully conducted experiments of Dr. Gerstley go far to reestablish confidence in a food substance which for quite unaccountable reasons had fallen into considerable disrepute as a carbohydrate component for the infant's food. It is always difficult to reconcile this attitude with the fact that this particular sugar is native to human and all forms of animal milk that are used in infant feeding. I think Dr. Gerstley has quite conclusively shown that it is entirely safe even in large percentages and that its metabolism generally proceeds in a favorable manner. Whether this sugar is superior to other sugars is not quite clearly brought out and will, I believe, need quite a little further experimental evidence. Dr. Gerstley's work is interesting from another point of view in that it furnishes experimental data in confirmation of recent clinical experience, that high sugar percentages in the infant's food are not dangerous but may even have the reverse effect from the one that was generally expected and formerly predicted. The pediatrician today seems to have passed from the era of low sugar feeding to one of high sugar feeding. All this has given a changing concept of the mechanism and the factors which probably underlie, and are largely responsible, for the development of the dangerous diarrheal state. Dr. Gerstley pointed out some of these factors and suggested the thought and expressed the opinion which many have that, in the development of the dangerous state of alimentary intoxication, the carbohydrate component of the diet is only quite indirectly concerned. The picture of severe intoxication without the development of diarrhea which he showed in some of his charts is one with which many are familiar. I believe that studies of the kind Dr. Gerstley has made are greatly needed in the pediatrics and medicine of today. I think they will go far to replace theory by fact and feel that they will help in the finding of reasonable explanations for what in the past were so commonly empiric procedures.

Biologic Basis of Human Nature.—It is known that each of the thousand genes is a distinctive substance, having a definite function, a particular work to do in producing the new individual; so that if any one of them is destroyed or changed, development is altered in a definite way, and the resulting individual shows a corresponding change in his characteristics: a change perhaps in the color of his eyes, the shape of his nose, his stature; or in his temper or temperament. It is known that each different kind of a gene has its regular and invariable place in the string. Thus the different genes can be named or numbered, and a particular one is always the same gene, with the same rôle to play, and found at the same place in the chromosomes. . . . Each of our parents gives us a complete set of genes, strung up in the way we have described. So we have in every cell two such strings of genes, each one complete in itself. We are therefore double with respect to our genes. Each of the two sets in a cell contains all the materials that are necessary for producing an individual: a fact that has strange consequences. The mother gives us all the materials required for producing an individual of a certain type; the father also gives us the materials for producing another individual of another type. So we start life as double individuals.—Jennings, H. S.: The Biological Basis of Human Nature, New York, W. W. Norton & Co., Inc., 1930.

STUDIES ON DIGITALIS IN AMBULATORY CARDIAC PATIENTS

IV. NEWER PRINCIPLES OF DIGITALIS DOSAGE *

HARRY GOLD, M.D.
AND
ARTHUR C. DeGRAFF, M.D.
NEW YORK

The practice of William Withering,[1] who published the first detailed study of digitalis about 150 years ago, is a matter not only of historical interest but of great practical importance to one dealing with the subject of digitalis dosage. At first glance it may appear as a stroke of genius that a fundamental law regarding the dosage of digitalis was stated at a time when practically nothing was known about the drug, not even that its beneficial effects were related to an action on the circulation. On the other hand, it may be the very fact that there were no distractions in the form of theories of cumulation and excretion or formulas of dosage that made it possible to keep the object clearly in view and to arrive at sound and practical principles. Physicians who profess to use a recommended plan of digitalis dosage frequently find their patients suffering from either insufficient or excessive digitalization. A common difficulty is illustrated by the following example: A physician recently made inquiry because, after having given a patient of a certain weight a daily dose of 4½ grains (0.3 Gm.) of digitalis for about three weeks, he found himself uncertain as to the next procedure when at the end of that time only moderate improvement had occurred and no toxic symptoms had resulted, although the total quantity had exceeded the dosage determined by an accepted method of calculation (Eggleston) and allowance was made for supposed daily excretion (Pardee). Withering's advice in such matters will bear frequent repetition: "Let the medicine be given until it either acts on the kidneys, the stomach, the pulse or the bowels; let it be stopped upon the first appearance of any of these effects." Expressed in modern phraseology, his recommendation was to give digitalis in dosage sufficient to produce the desired therapeutic results and to discontinue it when these are obtained or when minor toxic symptoms occur. In his monograph it is apparent that his practice was to give large doses at first and then to continue the treatment with smaller ones.

In the period of rationalization that followed this work, a great deal of knowledge was gained about the action of digitalis, but much confusion was also introduced by the substitution of *a priori* reasoning for painstaking clinical observations. Theories of cumulation instilled a fear of the drug that resulted in the use of such small quantities as 2 minims (0.12 cc.) of the tincture of digitalis three times daily. In a lecture before the Harvey Society in 1910, Cushny[2] deplored the common use of such inadequate dosage and stated that "The best results are obtained only by the largest doses which can be given without gastric or intestinal symptoms" and recommended doses of from 1 to 1½ drachms (4 to 6 cc.) of the tincture of digitalis daily. Eggleston,[3] in 1915, established the fact that even larger doses of digitalis may be given on the first day with a fair degree of safety, and frequently with great advantage under certain conditions, so that the full effects may be induced as early as eighteen hours after the oral administration of the dose. In 1922 Pardee,[4] in a paper dealing with the prolonged use of digitalis, expressed a view similar to Cushny's. He said: "We want as strong an action as the drug can exert, and so we try to continue the most effective degree of digitalization which is just short of poisoning." He advised that patients should first be brought to the point of saturation (to early toxic symptoms), should then, after an interval of a day or two, receive an average daily dose of 2 grains (0.13 Gm.) because he believed that the average patient excretes about 2 grains daily, and that that daily excretion dose "can and must be given in order to maintain the digitalis effect."

[2] Cushny, A. R.: The Therapeutics of Digitalis and Its Allies, Harvey Lectures, 1910-1911, p. 46.

In the reaction to the use of very small doses of digitalis, practice has exceeded the limits recommended by Withering. An altogether too simple view of the matter has been commonly accepted; namely, that in order to produce the best results, it is necessary to digitalize all patients to a point just short of minor toxic symptoms, and that in order to maintain these results it is necessary to maintain the same "effective concentration" of the drug in the body. In the present communication we shall relate how it came to be suspected that these views regarding digitalis dosage are wholly inadequate to explain the response to the drug of the large proportion of ambulatory cardiac patients and to set forth evidence that supports the following conclusions:

1. In the average ambulatory cardiac patient there is a wide margin between the amount of the drug necessary to produce full therapeutic effects and the maximum amount that can be tolerated without toxic symptoms.

2. The "effective concentration" of the drug within the body necessary to maintain full therapeutic results is usually much lower than that necessary to produce them in the beginning.

3. The average ambulatory cardiac patient with auricular fibrillation can be satisfactorily digitalized by the daily repetition of a relatively small dose of the drug, which can then be continued for months or years as the daily maintenance dose without producing toxic symptoms.

4. The degree of heart failure determines the "effective concentration" of digitalis in the body necessary to produce full therapeutic effects and the average ambulatory patient with symptoms of heart failure requires a much lower "effective concentration" of the drug to attain this result than the average bedridden patient with far advanced congestive failure.

CUMULATION, A SELF-LIMITING PROCESS

It is well known that if the average cardiac patient were to receive a daily dose of 9 grains (0.6 Gm.) of an active specimen of digitalis, there would result a progressive increase in the intensity of digitalis action that would continue until toxic symptoms appeared. This is usually interpreted as signifying that the daily dose of 9 grains is more than the patient can excrete in a day, so that the drug continues to accumulate until a quantity is present sufficient to produce toxic symptoms. In a previous article we[5] called attention to the fact that when smaller doses of digitalis are repeated daily it can be shown that cumulation is a self-limiting process; that a suitable daily dose may give evidence of cumulation at first, and that then a level is reached, the effects showing no further increase in intensity even though the same daily dose continues to be administered. The behavior of a typical case is shown[6] in chart 1.

This patient had auricular fibrillation and had been in bed with an attack of congestive heart failure. When he appeared at the clinic he had been without digitalis for a period of three weeks. The ventricular rate was 122 a minute and there were moderate symptoms of cardiac failure. He was given a daily dose of 3 grains (0.2 Gm.), which produced progressive slowing of the ventricular rate and improvement in the symptoms of failure. After two weeks the condition reached a level which was then maintained by the same daily dose without interruption during the succeeding period of forty-two weeks in which he was observed.

The level of effect reached in these cases may be considered as representing a quantity of digitalis which has accumulated[7] in the body and which shows no appreciable variations as long as the same daily dose is continued.[5] The size of the daily dose determines the point at which cumulation ceases (equilibrium between the daily dose and daily excretion). Thus, while a daily dose of 3 grains (0.2 Gm.) in a given patient may lower the ventricular rate from 140 to 80 a minute and keep it at 80, a daily dose of 2 grains (0.13 Gm.) may only lower the rate from 140 to 110 and keep it at that rate, or a daily dose of 6 grains (0.4 Gm.) may lower it from 140 to 50 a minute and keep the rate at this new level with continued administration of the drug. In order to simplify the discussion we shall refer throughout this paper to the amount of digitalis effective when a given level is reached as the "effective concentration" of the drug within the body.

MARGIN BETWEEN MINIMUM DOSAGE FOR FULL THERAPEUTIC EFFECTS AND MAXIMUM DOSAGE TOLERATED WITHOUT TOXIC SYMPTOMS

Several years ago we began to make observations in the Adult Cardiac Clinic of Bellevue Hospital on patients with auricular fibrillation with the view of determining the average daily dose of digitalis necessary to maintain the full therapeutic effects that had been induced while the patient was in the hospital, and to ascertain to what extent that dose would vary with preparations of different potency. During this period approximately 800 ambulatory cardiac patients with auricular fibrillation were treated. Many of them were working. They all showed varying degrees of deficiency in cardiac reserve and with few exceptions had received hospital treatment for one or more attacks of congestive heart failure. When these patients were discharged from the wards of the hospital and enrolled in the clinic, the usual procedure was to begin with a dose of 2 or 3 grains daily. The drug was dispensed in the form of compressed tablets of the dried digitalis leaf and the daily quantity was directed to be taken in a single dose.[9] The patients were examined at intervals of one week or less frequently, depending on a number of circumstances. If toxic symptoms resulted, the daily dose was diminished. The average ambulatory cardiac patient with auricular fibrillation constantly suffers with some symptoms due to deficient cardiac reserve; hence, when the initial dosage produced no symptoms, it was usually increased in an effort to obtain further improvement, and the only way to learn whether greater therapeutic effects were possible in a given patient was to increase the size of the daily dose gradually to the point of minor symptoms. When these occurred the dose was again diminished and the largest amount that produced no toxic symptoms was then continued as the daily maintenance dose. We had previously followed the accepted idea that it was necessary to administer digitalis in the largest doses that could be tolerated without toxic symptoms. At first the study embraced only those patients who attended the clinic regularly and took the daily dose with few or no interruptions.

[6] In all the illustrative cases in this paper, digitalis leaf (specimen F) was used with a potency of 100 mg. per cat unit.

[7] It is probable that cumulation is in part due to summation of effects in patients with heart failure.

[8] It is possible that some changes may result from the gradual cumulation of slowly excreted fractions of the drug while rapidly eliminated fractions do not cumulate to the same degree.

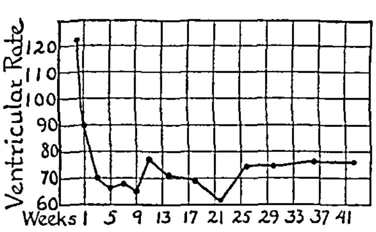

Chart 1.—Ventricular rate in patient E. Q., aged 25, weight 154 pounds (70 Kg.), with rheumatic heart disease, mitral stenosis and insufficiency, enlarged heart and auricular fibrillation; class II-a. The patient had had no digitalis for three weeks; class II-b. Three grains (0.2 Gm.) of specimen F was administered daily.

The first specimen of digitalis (specimen A) had a potency of 75 mg. per cat unit and was used for a period of about one and one-half years by the foregoing technic. It was then discontinued and a second specimen of digitalis (specimen C) was substituted and continued for about the same length of time. The potency of the second specimen was 140 mg. per cat unit. The initial trial doses of this specimen were usually the same in terms of grains as the final daily dosage of the first specimen, although the first was nearly twice as active as the second by the cat method of assay.

That specimen A was also much more active in man than specimen C was evident from the fact that some of the patients in the clinic showed signs of insufficient digitalization when the weaker preparation was substituted for the stronger one in the same grain dosage.[10] It was further confirmed by tests made on patients with congestive heart failure in the wards to whom 0.15 cat unit per pound of body weight of each preparation was given in a single dose. To some of these patients the stronger preparation was given first and, after an interval sufficient for the excretion of the drug, the weaker preparation was given in almost twice the quantity with practically identical results.

Two facts soon became apparent: First, while some of those patients who had been eliminated from the original study because they took digitalis irregularly suffered more marked symptoms of failure or gave objective evidence of inadequate use of the drug, it was rather striking that others showed no signs of insufficient digitalization. Second, the general condition of most of the patients was practically the same with identical doses in grains of the two preparations. As already stated, there were some exceptions in which larger doses of the weaker preparation had to be given to maintain the previous state of improvement.

An analysis was then made of a group of forty-six patients who had received the stronger preparation. The results showed the average daily dose to be 2³⁄₁₀ grains (0.15 Gm.). A similar analysis was made of a group of forty-two patients who received the preparation that was one-half as active. The results showed the average daily dose to be 2⁸⁄₁₀ grains (0.18 Gm.). With only few exceptions the two groups included the same patients and no patient was included who had not received each of the two specimens of digitalis for at least three months. It was also proved that these patients required digitalis because symptoms of failure appeared when the drug was withheld.

The foregoing facts therefore indicate that the average ambulatory patient with auricular fibrillation in whom improvement was maintained for long periods of time by what was approximately the maximum tolerated dosage was receiving much more digitalis than was necessary though no toxic symptoms were induced, and that much smaller doses sufficed to produce equally satisfactory therapeutic results.

This conclusion was tested in a somewhat different way in a number of cases in which the same specimen of the drug was employed in varying doses in the same patients. The results obtained in one case have been charted and serve as an illustration (chart 2). This patient had auricular fibrillation with moderate symptoms of congestive heart failure and a ventricular rate of 140 a minute. He had been without digitalis for a period of more than three weeks when he came under observation. After a daily dose of 3 grains (0.2 Gm.) for fourteen days the ventricular rate decreased to 81 a minute and all symptoms of failure disappeared. The continued use of this dose maintained this improvement. An increase of the dose by 100 per cent to 6 grains (0.4 Gm.) daily, produced no perceptible change in the condition. A further increase to 9 grains (0.6 Gm.) daily for seven days lowered the heart rate to 68 a minute, though the symptoms and signs remained the same. Thus the clinical condition during the period when the dose of 6 grains was taken was indistinguishable from that in which the one of 3 grains was used. This again illustrates the wide margin between the maximum tolerated dosage and that which is sufficient to produce or maintain the full therapeutic results in this class of patient.

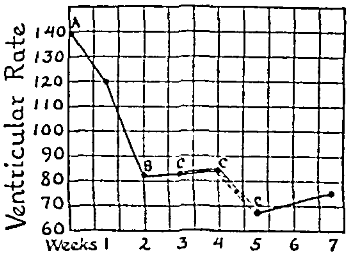

Chart 2.—Ventricular rate in patient J. H., aged 51, with rheumatic heart disease, mitral stenosis and insufficiency, enlarged heart and auricular fibrillation; class II-a. *A*, failure; *B*, marked improvement; *C*, same; the single line indicates 3 grains (0.2 Gm.) daily; double line, 6 grains (0.4 Gm.); three lines, 9 grains (0.6 Gm.).

In this chart, as in all the subsequent ones, only the ventricular rate is recorded as evidence of the intensity of digitalis action because it is a criterion that lends itself most satisfactorily to graphic presentation. The apex rate was counted by the stethoscope under fairly uniform conditions with the patient sitting or lying after a rest of several minutes. In most instances, other evidence of failure disappeared with the slowing of the heart rate. We have gathered data bearing on the relative importance of the various criteria for estimating the intensity of digitalis action in patients with auricular fibrillation and these will be analyzed in a subsequent communication. It is well to state here, however, that while the ventricular rate is a very satisfactory index of digitalis action in most cases of auricular fibrillation there are many cases in which the intensity of action is not revealed in changes of the ventricular rate alone. It is not infrequently observed that a given dosage lowers the heart rate to normal levels with only moderate improvement in the symptoms of failure, and with more intense digitalization the latter improve markedly though little or no further change in the heart rate occurs. On the other hand (with due caution against possible errors in interpretation), improvement in the subjective symptoms of failure is occasionally seen after doses of digitalis that have produced little or no slowing of a rapid ventricular rate.

[10] In these cases the dosage of specimen A may have been less than the maximum tolerated dose, or they may have been cases in which the latter is necessary to maintain the effects

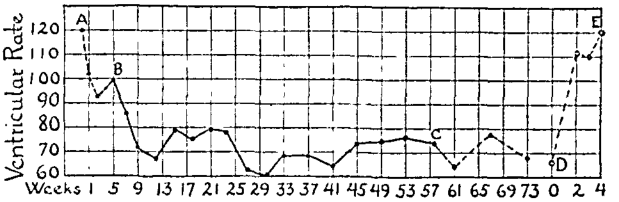

Chart 3.—Ventricular rate in patient T. K., aged 30, with heart disease of unknown origin, mitral stenosis and insufficiency, enlarged heart and auricular fibrillation; class II-a *A*, failure, class II-b, 3 grains (0.2 Gm.) of specimen F daily; *B*, 4½ grains (0.3 Gm.) daily; *C*, 3 grains; *D*, digitalis discontinued; *E*, failure; class II-b.

"EFFECTIVE CONCENTRATION" OF DIGITALIS FOR PRODUCING FULL THERAPEUTIC EFFECTS VERSUS "EFFECTIVE CONCENTRATION" NECESSARY FOR MAINTENANCE

In order to induce the full effects of digitalis without undue delay it is necessary to give relatively large doses for the first few days, and since these doses, if continued, will induce toxic symptoms, the treatment is continued with smaller daily doses. This is a generally approved practice. It is commonly held, however, that these smaller doses should be equal to the amount of digitalis the patient excretes daily after full digitalization, in order to maintain the high "effective concentration" of the drug in the body induced by the larger doses. The very fact that most ambulatory patients after having been fully digitalized in the hospital were getting along satisfactorily with nearly one-half as much digitalis as they could tolerate without toxic symptoms is in itself an indication that such an "effective concentration" as is often necessary to induce effects is frequently unnecessary in order to maintain them. A number of observations bearing directly on this question have been made and the results in a typical case are reproduced in chart 3. The observations on this patient covered a continuous period of seventy-three weeks for this study. The patient had auricular fibrillation and had been attending the cardiac clinic for more than five years. When receiving adequate doses of digitalis he usually presented only slight evidence of deficient cardiac reserve. At the end of the chart there is a record of the changes occurring when the drug was withheld after a daily dosage of 4 grains (0.26 Gm.) for some time. Within two weeks the ventricular rate became rapid and after four weeks marked symptoms of failure appeared. It is evident, then, that for this patient the more or less continuous use of the drug was essential. At another period he had received a daily dose of 1½ grains (0.1 Gm.) for several weeks. This dose was inadequate and he gradually passed into congestive heart failure with a ventricular rate of 120 a minute, as seen at the beginning of the chart. It now became necessary to digitalize the patient again. A daily dose of 3 grains (0.2 Gm.) for one week resulted in only moderate improvement and slowing of the heart rate to about 100 a minute, and the continuation of that dose for four more weeks simply maintained that level. The dose was then increased to 4½ grains (0.3 Gm.) daily with the result that the rate returned to a normal range and all symptoms of failure disappeared. This dose was then continued *daily for a period of fifty-three weeks without giving* any evidence of greater digitalis action. It was then diminished to 3 grains (0.2 Gm.) daily, which now served to maintain the state of improvement during the subsequent period of observation of nearly four months. Thus, it is shown that, contrary to the common belief, a lower "effective concentration" of digitalis within the body may suffice to maintain the full effects than may be required to produce them in the beginning; and, as has already been shown, that the daily dose necessary to maintain these effects may be much smaller than that which can be excreted daily.

DIGITALIZATION BY A SMALL DOSE METHOD

In previous articles we[11] called attention to the fact that ambulatory cardiac patients with auricular fibrillation showing a rapid ventricular rate and varying degrees of heart failure, who have never received digitalis or in whom it was withheld for sufficiently long periods of time to allow for elimination of the drug, can be effectively digitalized by the daily repetition of a dose which may then be continued daily for long *periods of time* (months or years) *without* producing toxic symptoms. The daily doses ranged from 2 to 6 grains (0.13 to 0.4 Gm.), being occasionally as high as 9 grains (0.6 Gm.), and varied with different patients and with differences in potency of the drug. The records of thirty-four satisfactory courses of digitalization in twenty-one patients were published and, since then, nine additional patients were proved[12] to have been fully digitalized[13] in that way. The behavior of

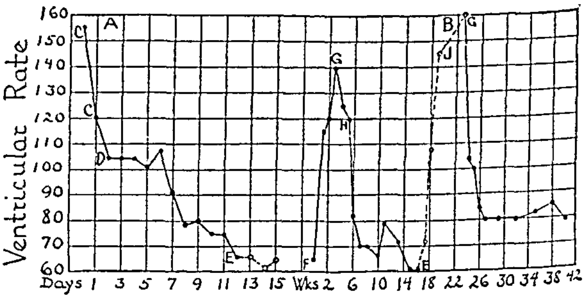

Chart 4.—Ventricular rate in patient J. R., aged 46, with arteriosclerotic heart disease, enlarged heart and auricular fibrillation. *A*, first failure (in hospital); functional class III; *B*, second failure (in clinic); functional class II-b, *C*, 24 grains (1.5 Gm.); *D*, 12 grains (0.8 Gm.) daily; *E*, digitalis discontinued; *F*, 3 grains (0.2 Gm.) daily; *G*, 6 grains (0.4 Gm.) daily; *H*, 9 grains (0.6 Gm.) daily; *J*, 4½ grains (0.3 Gm.) daily.

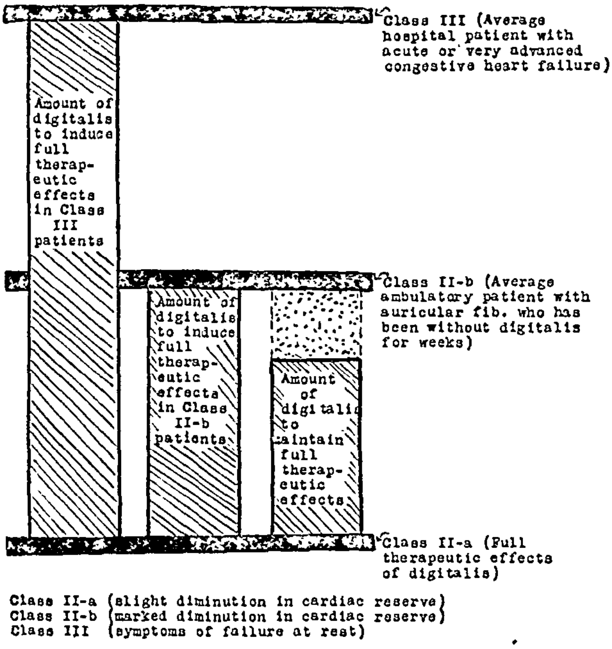
[11] Gold, Harry; and DeGraff, A. C.: (Footnote 5); Studies on Digitalis in Ambulatory Cardiac Patients: III. Digitalization by a Small Dose Method, J. A. M. A. **92**: 1421 (April 27) 1929.

[12] It has always been necessary to continue an experiment for several months in order to be fairly certain that the dose selected would not cause toxic symptoms. Only a small percentage of experiments started could therefore be completed satisfactorily and without interruption.

[13] In all cases suitable care was taken not to attribute to digitalis results that were due to changes in effort (footnote 5).

a typical case has already been shown in chart 1. It should be noted that the full therapeutic effects were induced by the same 3 grain (0.2 Gm.) daily dose that the patient was excreting daily during the long period of maintenance. If he had not been excreting it, toxic effects would have resulted from cumulation. This illustrates a departure from the view commonly held about the so-called daily excretion dose; the latter has been generally considered adequate to maintain effects produced by larger doses but not sufficient to produce them in the first place. In those papers we presented reasons for the belief that the foregoing phenomenon is explained by the fact that the amount of digitalis excreted daily is in all probability not a fixed quantity, and the dose that was excreted daily after some drug had accumulated in the body was not being completely excreted at the beginning.



Class III (Average hospital patient with acute or very advanced congestive heart failure)
Amount of digitalis to induce full therapeutic effects in Class III patients
Class II-b (Average ambulatory patient with auricular fib. who has been without digitalis for weeks)
Amount of digitalis to induce full therapeutic effects in Class II-b patients
Amount of digitalis to maintain full therapeutic effects
Class II-a (Full therapeutic effects of digitalis)
Class II-a (slight diminution in cardiac reserve)
Class II-b (marked diminution in cardiac reserve)
Class III (symptoms of failure at rest)

Chart 5.—Dosage of digitalis that is necessary to produce full therapeutic effects varies with the degree of heart failure.

DEGREE OF HEART FAILURE A FACTOR IN DOSAGE

While the larger proportion of ambulatory cardiac patients with *auricular fibrillation can be successfully* digitalized by the "effective concentration" of the drug reached by the daily repetition of relatively small doses, there is ample experience to show that such daily quantities are quite inadequate to induce full therapeutic effects in most patients with very advanced congestive heart failure. That the degree of heart failure is an important factor in determining the amount of digitalis necessary to produce full therapeutic results has been further tested in a number of observations, of which the following is an illustration (chart 4). This patient had auricular fibrillation and was admitted to the hospital in advanced congestive heart failure with a rapid ventricular rate. During a control period in bed for nineteen days the condition did not improve appreciably. He then received large daily doses of digitalis, 24 grains (1.55 Gm.) daily for the first two days, then 12 grains (0.78 Gm.) daily, with the result that marked improvement occurred, the ventricular rate slowed, the edema disappeared with a loss in body weight of about 30 pounds, or 13.6 Kg. (170 pounds to 140 pounds, 77 Kg. to 63.5 Kg.) and the patient was up and about after the sixth day. After his discharge from the hospital a daily dose of 3 grains (0.2 Gm.) for three weeks was insufficient to maintain the effects, and then a daily dose of 6 grains (0.4 Gm.) for two weeks was inadequate to restore the results obtained in the hospital. It was increased to 9 grains (0.6 Gm.) daily and this resulted in full digitalization, which was maintained for eleven weeks by the same daily dose. The drug was then withheld and at the end of five weeks moderate symptoms of failure and a very rapid ventricular rate developed. This time the daily administration of 6 grains (0.4 Gm.) of the same specimen of the drug was sufficient to produce full digitalization and to maintain the effects for a period of observation of sixteen weeks. In this patient, therefore, when failure began to reappear shortly after his discharge from the hospital as the result of an inadequate maintenance dose of digitalis, a daily dose of 6 grains (0.4 Gm.) was insufficient to check it appreciably. This dose, however, was quite sufficient to digitalize the patient satisfactorily in a mild attack of failure after a prolonged period of several months of improvement.

The conception that develops from these observations regarding the "effective concentration" of digitalis neccessary under different conditions is represented schematically in charts 5 and 6. It may be seen from chart 5[14] that patients with very advanced congestive heart failure require more digitalis to produce full therapeutic effects than those with symptoms of failure of lesser degree. A corollary of this fact is the further observation that the "effective concentration" necessary in order to produce the full effects is frequently much higher than is necessary in order to maintain them. These facts are illustrated from a somewhat different angle in chart 6. It shows that while there is a wide margin between the dose necessary

for full therapeutic effects and that which produces toxic symptoms in patients with moderate symptoms of failure, this margin is often very small in patients with acute or very advanced congestive heart failure. In the latter, the margin is sometimes rendered even smaller by the greater susceptibility to some of the minor toxic symptoms, such as premature contractions. This is frequently seen in the terminal stages of heart disease.[15]

THE AMBULATORY CARDIAC PATIENT VERSUS THE BED PATIENT

For practical purposes it is well to consider two general groups of patients with auricular fibrillation presenting symptoms of heart failure. One is the type generally found in the wards of the hospital; the other is the ambulatory patient of the cardiac clinic. There is, of course, no sharp distinction between the two, and a given patient may at different times belong to one group or the other. The classification is employed to convey the idea of the distinction between patients with acute or far advanced heart failure showing marked symptoms at rest, and those that have more moderate symptoms, or symptoms only after exertion, who are able to be up and about, or may even be engaged in some light occupation. As already stated, it has been abundantly demonstrated that rapid digitalization with large doses frequently gives the best results in the very advanced degree of failure of the hospital patient. In this type the amount the patient needs is frequently the largest that can be tolerated without toxic symptoms. In the average ambulatory patient, however, such a high "effective concentration" is usually unnecessary. A much lower "effective concentration" produces equally satisfactory therapeutic results, though the higher one can be tolerated for years without showing any greater therapeutic results or producing any toxic symptoms.

We have used the term "equally satisfactory therapeutic results" while at the same time appreciating the fact that the present available criteria are quite inadequate for determining when results are equally satisfactory in every respect. There are at least three important factors to be considered: the subjective symptoms, the objective signs of failure, and the tendency to recurrence of attacks of failure. If a patient with auricular fibrillation with marked dyspnea, edema of the legs and a ventricular rate of 140 a minute is given a daily dose of 4½ grains (0.3 Gm.) of digitalis, and after ten or fifteen days all the shortness of breath and the edema disappear, the ventricular rate reaches a normal range around 75 or 80 a minute, the patient resumes his former work, and the state of improvement is maintained for several months, we say that the full therapeutic results have been produced, provided no greater improvement is in evidence when the dose is increased. When similar results are obtained by a daily dose of 3 instead of 4½ grains, in the same patient, the question arises whether the smaller dose will be as effective as the larger one in preventing the recurrence of heart failure in the course of years. There have been no systematic studies of this question and it is hardly necessary to state that such an investigation, though difficult to carry out, would yield information of great practical value. In the present state of knowledge it is more logical to follow the principle of digitalis dosage laid down by Withering, which is not to give as much digitalis as patients can tolerate without toxic symptoms, but only so much as is necessary to produce full therapeutic effects judged by the available criteria of improvement.

PRIMARY AND SECONDARY DIGITALIS EFFECTS

The phases of the problem of dosage for the production and maintenance of digitalis effects that have been discussed are, we believe, merely different aspects of the primary idea that the degree of heart failure determines the necessary dosage.[16] The probable explanation of the fact that patients with extreme heart failure usually require a higher "effective concentration" of digitalis in the body to restore the circulation than the same patients in a lesser degree of failure is closely bound up with the subject of the duration of digitalis effects and will be discussed in a forthcoming paper dealing with that subject. Suffice it to say at this time that neither differences in absorption nor excretion of the drug in the two states of heart failure appear to be factors of any great importance in the majority of cases. The production and the maintenance of digitalis effects in patients with congestive heart failure is not to be regarded as a case of simple biologic titration with a drug, in the sense that a given dose produces a given effect and that with the disappearance of the drug the effect at once disappears. After the circulation is restored by digitalis (primary effect), an important secondary factor becomes apparent; namely, the tendency to remain improved independently of the drug. This varies with different kinds and degrees of cardiac damage and in all probability plays a significant rôle in determining the "effective concentration" of digitalis that is necessary to produce as well as to maintain full therapeutic results.

There are wide variations in the amounts of digitalis recommended by different authorities. This is partly due to the fact that preparations of different potencies are employed, often affording no basis for comparing actual dosage. This subject is discussed in a recent paper by Wyckoff, Gold and Travell.[17] They also pointed out that differences in the potency of different preparations may sometimes escape detection in the wide margin between the minimum doses that produce the full effects and the maximum doses that can be tolerated without toxic symptoms. Another important source of confusion regarding dosage, however, is the fact that patients with symptoms of heart failure have been regarded in the past as a homogeneous group from the standpoint of their needs for the drug. At a time when very large doses were considered dangerous, patients with far advanced cardiac failure were inadequately treated, whereas at the present time, when digitalization to the point of minor toxic symptoms has come to be generally regarded as essential, the average ambulatory patient with mild symptoms of cardiac failure is receiving far more digitalis than is necessary.

SUMMARY

1. In the average ambulatory cardiac patient with auricular fibrillation and moderate heart failure a much lower "effective concentration" of digitalis in the body suffices to produce full therapeutic effects than is required in the average bedridden patient in advanced congestive failure.

2. We have shown that, in the ambulatory patient, full therapeutic effects, as judged by the usual clinical

criteria of improvement, can be produced by daily repetition of a relatively small dose of the drug that can then be continued as the daily maintenance dose without producing toxic symptoms. As is well known such results cannot be obtained with such small doses in the average patient with far advanced congestive failure; the larger daily doses usually required in these cases cannot be long continued without producing toxic symptoms.

3. In the average ambulatory cardiac patient there is a wide margin between the minimum dosage that produces full therapeutic results and the maximum that can be tolerated without toxic symptoms. This margin is frequently smaller in patients with far advanced failure and the latter often require the largest dosage that can be tolerated in order to produce the best results.

4. It is the accepted practice to use relatively larger doses of digitalis to produce the full therapeutic effects and then relatively smaller daily ones in order to maintain these results for long periods of time. The usual explanation is that the smaller doses are necessary in order to maintain the high "effective concentration" of the drug produced by the larger ones. Evidence has been set forth proving, however, that the "effective concentration" of the drug within the body necessary to maintain the full effects is usually much lower than that required to produce them in the beginning.

THE THERAPEUTIC VALUE OF DIGITALIS IN PNEUMONIA *

JOHN WYCKOFF, M.D.
EUGENE F. DU BOIS, M.D.
AND
I. OGDEN WOODRUFF, M.D.
NEW YORK

The work of Cohn and Jamieson [1] definitely established that there is a digitalis action on the heart in lobar pneumonia. In an address given in 1916 on the use of digitalis in pneumonia, Cohn [2] concluded that this drug did no harm and might be life saving. He suggested that it might be given to all patients as a routine, and explained the method of dosage in operation at the Hospital of the Rockefeller Institute. This extremely careful work and these conservative suggestions naturally influenced medical thought throughout the country, so that during the next ten years the routine giving of digitalis to patients with lobar pneumonia became a not uncommon procedure in many clinics, including Bellevue Hospital and most of the other large hospitals in New York.

However, during the period in which digitalis was given, no studies of comparative mortality were made between groups of patients with pneumonia receiving digitalis, and others from whom it was withheld. In Bellevue Hospital the study by the Columbia, Cornell and New York University Medical Divisions in the cases of lobar pneumonia with reference to specific antipneumococcus therapy by the control method provided a machinery that could readily be adjusted to include an investigation of the effects of the use or nonuse of digitalis as routine therapy in this disease as well. It seemed, therefore, an ideal time to investigate the action of the drug in cases of pneumonia, through the opportunity to use methods more favorable to constructive conclusions than had hitherto been employed.[3]

METHOD

In other studies of the value of digitalis in pneumonia there were none in which simultaneous observation under identical conditions were made on similarly selected groups of patients treated with digitalis and patients from whom digitalis was withheld. If sound conclusions are to be drawn, it is essential that both groups of patients, those receiving digitalis and those from whom digitalis is withheld, be selected similarly and simultaneously.

The analysis of hospital records of previous years with the study of digitalis untreated and treated groups does not constitute a properly controlled series. As a rule, under these circumstances, digitalis was not given in the milder cases of pneumonia, while it was thought necessary in the more severe cases and the patients were given it. This fact is well brought out by Randolph [4] in his analysis of 100 consecutive cases at the George Washington University Hospital, by Cohn and Jamieson [1] in their study of 105 cases at the Rockefeller Institute, and by Burrage and White [5] in their analysis of 221 cases during a five year period at the Massachusetts General Hospital. A further method of selection of controls, as done by Hart [6] in his study of influenzal pneumonia, in which a considerable number of controls "were selected at random from time to time," does not seem satisfactory. Nor yet does the comparison of untreated cases observed during one period of time with cases treated with digitalis during another period seem justified, as was done by Stone, Phillips and Bliss,[7] and later again by Stone,[8] since other methods of treatment as well as virulence of infection differ greatly from time to time.

In the present study it was decided that patients should be selected for the digitalis or nondigitalis groups in the following way: Patients were received into the "pneumonia series" according to the date and hour of admission, and alternate patients were treated with serum. The combination of serum and digitalis therapy led to the grouping of patients into four classes, selected only by the time of admission, and termed arbitrarily A, B, C and D. The treatment of the patients in these four classes was as follows:

Class A received neither serum nor digitalis.
Class B received serum only.
Class C received digitalis only.
Class D received both serum and digitalis.

This system of classification operated in each ward independent of other wards, so that factors of general care and nursing might be the same for each class of treatment.

Criteria of diagnosis were those ordinarily used to establish the diagnosis of lobar pneumonia; namely, typical history, physical observations, characteristic sputum, pneumococcus typing and fluoroscopic examination, verified whenever possible by postmortem examination. In the first year of the digitalis study (1927-1928), all cases of lobar pneumonia were included in the series regardless of the duration of the disease on admission or of general complications. In the second year (1928-1929), cases with history of onset more than eight days previous to admission or with general system disease were excluded from the digitalis-serum series; but of the cases thus excluded, any that showed evidence of cardiocirculatory disease were studied in the digitalis series as extra cases and were treated with or without digitalis according to the time of their admission, with reference to the regular A, B, C and D grouping.

In a large, active service such as that at Bellevue Hospital, it is difficult under ordinary circumstances to be certain that medications are always given exactly in the form and at the hour ordered, but in this special study every precaution was taken to know precisely how and when the digitalis was administered. The "digitalizing dose" for each patient was put in a small cardboard box labeled with the patient's name and given to the nurse in charge of the ward. The order for digitalis was written both in the ward and in the order book and on a manila tag fastened securely to the patient's bed. When the nurse gave the digitalis, she initialed the tag and wrote on it the exact hour of administration. These tags, later collected, constituted a permanent record.
